of 'required mitigation.' Estimates of the impacts associated with oil and gas development vary widely, due in part to the nature of the development and the species and systems potentially impacted. To generate an estimate of impacts associated with an 'average well,' we examined data available from oil and gas development in the WBE. Estimates of direct disturbance from several US Bureau of Land Management's environmental impact assessments suggest that ~2.5 ha (~6 acres) of disturbance is associated with each well's well pad, roads, and pipelines (US BLM, 2006, 2007). Studies that have examined indirect estimates of disturbance suggest that upward of ~24 ha (~60 acres) of disturbance is associated with each well (Sawyer, 2009; Doherty *et al.*, 2010; Copeland *et al.*, 2009). Although we recognize that impacts of development extend beyond the footprint of direct surface disturbance, we chose a conservative estimate of 4 ha (10 acres) of disturbance impact for each well and required that offsets for these impacts be implemented.

We simplified the analysis in other ways as well. We recognize that offsets do not typically deliver conservation value per unit area equal to the area that is lost as a result of development. Under the DbD framework, we would strive to require that offset benefits are estimated using the principles discussed in step 4 to ensure that offsets deliver additional conservation that can be appropriately valued. For simplicity in this analysis, we used a 3 : 1 replacement ratio established as part of the only oil and gas development project in the WBE that has required offsite mitigation (US DOI, 2006, Kiesecker *et al.*, 2009). Offset activities can span a variety of actions from restoring degraded habitats to protecting habitats from future degradation. In the WBE, one of the key threats to biodiversity is the conversion of large working ranches to small ranchettes or residential subdivisions (Gude *et al.*, 2007). Easements are an effective tool for preventing habitat conversion of private lands and the only form of mitigation we considered in this analysis (Kiesecker *et al.*, 2007; Pocerwicz *et al.*, 2011). Although under the DbD framework we would consider a variety of offset actions, for simplicity we consider only private land conservation easements and compared the amount of private land conservation occurring from nonmitigation-related conservation to new private land conservation resulting from DbD related mitigation. We used the Protected Areas Database of the US (PAD-US v1.2) created by USGS GAP (<http://gapanalysis.usgs.gov/data/padus-data/>) to assess the quantity of protected private lands. We supplemented these data with locally available data (e.g., The Nature Conservancy) on additional known privately conserved lands in the project area. Approximately 10% of the available privately protected areas data had no date to indicate when a protection mechanism was placed on the land. In those cases, we redistributed acres proportionately across the three decades, starting in the 1980s when it is most probable that the private land conservation would have occurred. Consistent with

the DbD framework, before estimating the amount of impacts associated with development and the amount of offsets needed to compensate for these impacts, we first sought to indicate which wells would have been incompatible with landscape conservation goals and should have been avoided. To decide which impacts should have been avoided, we followed the approach outlined in Kiesecker *et al.* (2010) and described in the preceding step 2.

Our analysis indicated that more than 55,000 oil and gas wells have been drilled in the WBE, with 41,072 of these drilled since 1969 and subject to our application of DbD. The pattern of development shows a marked increase in the number of wells over time, with a low of 5542 wells drilled from 1970 to 1979 and a high of 17,761 wells drilled from 2000 to 2009 (Figure 5). Strikingly, only 2886 (~7%) of all wells were drilled in areas where our DbD analysis would have recommended that impacts be avoided. Wells compatible with landscape-level conservation goals would have resulted in impacts totaling 154,533 ha (381,860 acres) based on a estimated footprint of 4 ha (10 acres) per well. If we required 3 ha of offset for every hectare of impact, we would have generated 463,599 ha (1,145,580 acres) of additional private land conservation. Compare this with the 87,412 ha (216,000 acres) of private land conservation conducted over the same period; we see application of DbD results have a more than fivefold increase in conservation (Figure 5). We recognize this analysis incorporates simplifying assumptions; a more robust approach would consider a range of other factors such as how restoration actions may be addressing energy development impacts and contributing to conservation values, as these impacts are unlikely to persist indefinitely. Although there are limited data on the efficacy of restoration, if we assume a 30% restoration rate per decade then impacts would be reduced to 108,173 ha (267,302 acres) (Figure 5). Nonetheless, we believe this retrospective application of the DbD framework shows how, if DbD had been implemented as part of normal practices associated with energy development over the past four decades, it could have contributed to significant benefits for sage grouse as well as other species and perhaps alleviated current restrictions placed on energy development. Consider that if the impacts of wells incompatible with conservation goals (7% of wells) had been avoided and offsets had been implemented for wells compatible with conservation goals (93% of wells), then the WBE would have 498,637 ha (1,232,160 acres) more in valuable protected wildlife habitat. This represents 7.5% of all core sage grouse habitat in the WBE and 13% of the private lands within sage grouse core areas (Doherty *et al.*, 2011). If these additional conservation efforts had been targeted at sage grouse and other species of conservation concern, then we might not be facing the current uncertainties regarding listing under the Endangered Species Act and the consequences that would have for future energy development.

Figure 5 Applying Development by Design retroactively in the Wyoming Basins Ecoregion. Map shows location of wells, private land conservation, and additional private land conservation resulting from "required offsets". The number of wells drilled per decade is shown from 1969 to the present. Impacts associated with development are based on an estimate of 4 ha footprint per well. Additional private land conservation resulting from "offsets" is compared to existing private land conservation. Estimates of additional private land conservation are based on a requirement of 3 ha offset for each hectare of impact. For simplicity, additional private land conservation resulting from "offsets" were clustered around existing private land conservation.

Conclusion

Offsets represent an opportunity to mobilize billions of dollars for conservation (Burgin, 2008; McKenney and Kiesecker, 2010). If we ensure that development is consistent with broader conservation goals, avoiding impacts where they are not, then development can be the fuel to achieve significant conservation outcomes. The results of our simple analysis suggest that when offsets are a normal part of project activities, as regular practice for fully internalizing project impacts, then the level of conservation can exceed traditional sources by many multiples. Although incorporation of offsets into normal practices could obviously have benefits for conservation, it could also benefit development activities. Given the extensive amount of development projected for the WBE, a requirement for development to attain no net loss through application of DbD could be the impetus to conserve biodiversity and proactively add the flexibility needed to develop resources. This will be important as the US moves to exploit more of its domestic energy resources, particularly renewable energy (McDonald *et al.*, 2009; Kiesecker *et al.*, 2011b). Moreover, global development patterns suggest that changes projected for the WBE are closer to the rule rather than the exception. Lessons learned here could have implications for designing development that are compatible with nature and human well-being, reducing conflicts for both biodiversity conservation and business.

Glossary

Adaptation Actions that reduce the consequences of invasive species damage.

Comparative statics Comparing economic outcomes both before and after a change in an underlying exogenous parameter.

Control Controlling invasive species population or spread to reduce the damage an invasive species causes after becoming established in a new habitat.

Endogenous risk The idea that private citizens and public servants have some control over the set of probabilities and outcomes that define the relevant states of the world.

Feedback loop An ecological response to a human action having environmental consequences, followed by a human behavioral response to ecological changes having economic consequences.

Joint determination Ecological and economic systems are both affected by, and affect, each other.

Optimal control theory A technique used to study problems involving optimal decisions in a multiperiod framework.

Prevention Efforts to reduce the probability of an invasive species being introduced and subsequently becoming established in a new habitat.

Introduction

Invasive species destroy key natural resources used to produce market and nonmarket goods and services causing damages that outweigh any benefits they may generate (Elton, 1958; Kareiva, 1996; Lodge *et al.*, 2009). Their expanding global numbers play a primary role in global environmental change (ESA, 2004; Mack *et al.*, 2000; Sala *et al.*, 2000). In response, invasive species policies have expanded in scope and magnitude. For instance, in the USA, Executive Order 13112 points out the need to “minimize the economic, ecological, and human health impacts that invasive species cause” (also see Miller and Fabian, 2004; National Invasive Species Counsel (2001); CENR, 1999; FICMNEW, 1998). Internationally, countries can propose trade restrictions to prevent introductions of invasive species through the World Trade Organization’s (WTO) Agreement on Sanitary and Phytosanitary (SPS) measures (see Peterson and Orden, 2008; Calvin and Krissoff, 1998; Josling *et al.*, 2004; Smith, 2003).

For these public policies to be cost-effective, they should be informed by both economic and ecological principles (Finnoff *et al.*, 2009a, b, 2010a, b). Invasive species risks are jointly determined by economic and ecological interactions (Crocker and Tschirhart, 1993). Economic activity introduces many invasive species who find the new ecosystem suitable; they then spread through natural migratory patterns or hitch-hiking on commerce and recreation. Both economics and ecology and the feedback loops between the two systems play a key role (feedback loops here are defined as ecological responses from human actions having environmental consequences, followed by human behavioral responses to ecological changes having economic consequences). Effective public policy also requires detailed knowledge about the portfolio of risk reduction

technologies – prevention, control, and adaptation (see Shogren, 2000). (These guiding principles have generated an explosion of bioeconomic research, as shown in special issues of *Ecological Economics*, Volume 52, 2005; *Agricultural and Resource Economics Review*, Volume 35, 2006; and *Resource and Energy Economics*, Volume 32, 2010, a book edited by Keller *et al.* (2009) and a book edited by Perrings *et al.* (2010).) This article defines “prevention” as investments to reduce the probability of an invasive species being introduced and subsequently becoming established in a new habitat; “control” is defined as actions to curtail invasive species population or spread to reduce the damage an invasive species causes after becoming established in a new habitat; “adaptation” is defined as actions to reduce the consequences of invasive species damage.

This article combines the idea of *endogenous risk* into an optimal control setting to provide a framework to address the challenge on how to best manage the prevention and control of invasive species (Kamien and Schwartz, 1991). Endogenous risk captures the idea that private citizens and public servants have some control over the set of probabilities and outcomes that define the relevant states of the world (Ehrlich and Becker, 1972; Shogren and Crocker, 1991). The dynamic endogenous risk approach used here captures the following: (1) the biological and economic circumstances of invasions, (2) the interdependency of economic and ecological systems, and (3) accounts for inherent uncertainty associated with the bioeconomic parameters. This framework provides a means to identify the feedback loops between systems and to evaluate the trade-offs inherent in designing and implementing cost-effective public policies directed at the threats of invasive species. The discussion begins by presenting the problem of invasive species in the dynamic endogenous risk optimal control framework.

Optimal Control of Invasive Species

When considering how to manage renewable natural resources cost-effectively over time, economists typically use dynamic optimization, the most common variant being optimal control theory (for a primer in this setting, see [Kamien and Schwartz, 1991](#); [Lewis et al., 2009](#)). Economists use optimization techniques either to maximize net benefits (benefits from a management plan net its costs) or to minimize costs of the management plan. The optimal control method provides the derivation of an optimal jointly determined evolution of state variables (e.g., invader abundances) and control variables (prevention, control, and adaptation). (Examples include [Barbier \(2001\)](#), [Eiswerth and Johnson \(2002\)](#), [Olson and Roy \(2002, 2008\)](#), [Barbier and Shogren \(2004\)](#), [Knowler and Barbier \(2005\)](#), [Burnett et al. \(2006, 2008\)](#), [Kim et al. \(2006\)](#), [Potapov et al. \(2007\)](#), and [Finnoff et al. \(2010b\)](#)).

In the standard setting, the invasive species problem is cast as a renewable resource problem in which a single control is chosen to maximize the negative of a discounted stream of damages and control costs ([Eiswerth and Johnson, 2002](#); [Finnoff et al., 2010b](#)). The result is an optimal path for control that is monotonic in invasion size, yet typically exhibits features such as multiple equilibria that make the evaluation of optimal policies difficult (see [Olson and Roy, 2008](#), for a discussion). The standard optimal control setting is extended to one that incorporates endogenous risk in the spirit of [Shogren \(2000\)](#), as in [Horan and Fenichel \(2007\)](#). The dynamic endogenous risk framework incorporates more of the key risk reduction strategies that are available to managers.

Consider a benevolent resource manager charged with managing the risks of invasion. Following [Jerde and Lewis \(2007\)](#), [Figure 1](#) details the invasion process as a series of stages. Individual members of the invasive species are initially transported from a population in a source region. Some fraction survives, providing a dispersal pool of individuals. A fraction of the dispersal pool is then introduced into the region of interest from which some fraction can further spread and cause damage. Depending on the species and circumstances of the invasion process, the relative importance of each of these stages varies.

At a basic level there are three public policies (or management strategies) available to the resource manager in response to the risk. The manager can employ strategies that lower the probability of transport and introduction, a catch-all strategy termed *prevention*. Following introduction, the manager can use strategies that *control* the invasion to stop or slow

the spread and subsequent damage from the invader. Finally, the manager can *adapt* to the consequences of the invader and employ strategies that alleviate the realized damages. Although prevention and control work to inhibit the spread and damage of the invader, adaptation does not influence the growth and spread of the ecological process of a specific invasive species (note that adaptation might affect the ecological process of some future invader and also the incentives for control).

This article divides the management problem into two separate, though interrelated, time intervals. Specifically, it splits the ecological invasion process in [Figure 1](#) in half, so that invasion occurs at time τ . This partition also separates management into two stages: prevention occurs prior to time τ , whereas control and adaptation occur after time τ . The time of invasion τ is a random variable that can be delayed by the manager's investments in prevention. There are no damages during preinvasion (i.e., when $t < \tau$), although costly investments in prevention help avoid or delay future damages. Following an invasion ($t \geq \tau$), realized damages and social welfare depend on the manager's choices of control and adaptation in response to the invasion, as typically seen in the standard model of controlling an established invasion (which ignores prevention).

To include all of these features in a single model, the standard model of controlling an established invasion is merged with a rigorous treatment of the uncertainty underlying the timing of invasion and its prevention. This extension follows the model developed by William [Reed \(1987\)](#) for the optimal preventative maintenance schedule of a revenue-earning asset subject to random catastrophic failure. The method states the stochasticity of the problem in such a manner that deterministic methods of optimal control can be used to find a solution (see [Reed and Heras, 1992](#), for applications toward natural resources and [Horan and Fenichel, 2007](#), for an epidemiological application). [Kim et al. \(2006\)](#) present a variant of the method directed at invasive species, but they do not focus on differentiation in timing of prevention and control. [Burnett et al. \(2006, 2008\)](#) employ alternative frameworks that include prevention and control in which prevention works to prevent repeated introductions.

Here Reed's method is used to illustrate what are believed to be the key features in the economics of invasive species that can be addressed with the use of optimal control theory. Consider a natural asset or resource that generates a flow of social benefits in each period prior to invasion ($t < \tau$) given by $B(t)$. If an invader is able to successfully establish and cause damage (at time $t = \tau$ and beyond), then the benefits are

Figure 1 Flow diagram of the invasion process.

diminished by damages $D(X(t))$, where the invader stock is given by $X(t)$, where $X(t)=0$ before the invasion at time $t=\tau$ and $X(\tau)>0$. Greater levels of X lead to greater damages so that $(\partial D/\partial X)>0$. Expenditures on prevention $n(t)$ reduce net benefits before the invasion, V , so that

$$V(B, n, t) = B(t) - n(t) \quad [1]$$

These expenditures also reduce the probability of invasion and so the realization of damages. Following Reed (1987), the probability the invader is introduced at any time t , given that it has not been introduced up to that point in time, is given by the effective hazard function

$$\psi(n(t), b(t)) = \lim_{\Delta t \rightarrow 0} \{Pr(\text{Invasion in } (t, t + \Delta t) | \text{no invasion at } t) / \Delta t\} \quad [2]$$

where $b(t)$ is the background hazard or probability of invasion in the absence of prevention. The greater the background probability of invasion, the greater the hazard $\psi_b > 0$ and the more the prevention reduces the hazard $\psi_n < 0$ (where subscripts indicate partial derivatives in what follows). The probability of no invasion having occurred up to time t is given by the survivor function

$$S_p(t) = e^{-\int_0^t \psi(n(t), b(t)) dt} = e^{-\gamma(t)} \quad [3]$$

where the change of variables allows one to define $\dot{\gamma} = \psi(n, b)$, $\gamma(0) = 0$ so that $S_p(0) = 1$.

Following an invasion at time τ , the invader stock grows following a density-dependent growth function $F(X(t))$. Control expenditures $h(t)$ reduce or reverse the growth in the invader following an invasion through a “kill function” $K(h(t))$ so that

$$\dot{X} = F(X(t)) - K(h(t)), \quad X(\tau) = X_\tau, \quad t \in \{\tau, \infty\} \quad [4]$$

More money spent on control can be expected to remove more of the invader, so $K_h > 0$. Adaptation expenditures $a(t)$ simply lower realized damages while allowing the invader stock to remain so that $D(X(t), a(t))$ with partial derivatives $D_X > 0$ and $D_a < 0$. Let the flow of social net benefits from time τ onward be given by VX so that

$$VX(B, X, a, h, t) = B(t) - D(X(t), a(t)) - h(t) - a(t) \quad [5]$$

The expected net present value of net benefits earned over an infinite horizon is given by

$$J = E_\tau \left\{ \int_0^\tau e^{-rt} V(n, t) dt + \int_\tau^\infty e^{-rt} VX(X, a, h, t) dt \right\} \quad [6]$$

where the expectations operator reflects the uncertainty of invasion time τ and r is the discount rate. If one defines the present value of an optimal program of *ex post* management from τ through time to be given by $JX^*(X(\tau)) = \max_{h, a} \int_\tau^\infty e^{-rt} VX(X, a, h, t) dt$ (where the star indicates the function has been optimized by the optimal choices of $h^*(t)$ and $a^*(t)$ through time), it can be seen that JX^* depends on *ex ante* management through prevention before τ through both the point in time that damages begin to accrue and the initial stock of the invader in τ . $JX^*(X(\tau))$ is the solution to the standard renewable resource model of an optimally controlled invasion as developed in Eiswerth and

Johnson (2002), Brown *et al.* (2002), Lichtenberg and Lynch (2006), Burnett *et al.* (2006, 2008), Potapov *et al.* (2007), and Finnoff *et al.* (2010b). First the *ex ante* management schemes are discussed, and then the insight provided by optimal control for *ex post* management is explored.

Ex ante Management: Prevention

Rewriting eqn [6] allows the objective function for *ex ante* prevention to be written as

$$\max_n E_\tau \left\{ \int_0^\tau e^{-rt} V(n, t) dt + e^{-r\tau} JX^*(X(\tau)) \right\} \quad [7]$$

Following the steps laid out in the Appendix A, eqn [7] can be rewritten in a manner similar to that provided by Reed and Heras (1992)

$$J = \max_n \int_0^\infty [V(n, t) + \psi(n, b) JX^*(X(t))] e^{-rt - \gamma(t)} dt \quad [8]$$

subject to $\dot{\gamma} = \psi(n, b)$, $\gamma(0) = 0$, and the equation of motion in eqn [4]. The method results in a problem of deterministic optimization (Reed, 1987) that can be solved applying Pontryagin's maximum principle (see Kamien and Schwartz, 1991). The beauty of the method is that it incorporates the endogenous risk of invasion directly into the associated conditional current value Hamiltonian

$$\bar{H} = V(n) + \psi(n, b) JX^* + \rho \psi(n, b) \quad [9]$$

where ρ is the costate variable for γ . This deterministic formulation allows the application of the maximum principle (Pontryagin *et al.*, 1962). The associated necessary conditions require prevention to be chosen along the optimal path to maximize the conditional current value Hamiltonian

$$\frac{\partial \bar{H}}{\partial n} = V'(n) + \psi_n [JX^* + \rho] = 0 \quad [10]$$

given the evolution of γ follows

$$\dot{\gamma} = \psi(n, b), \quad \gamma(0) = 0 \quad [11]$$

and the evolution of ρ is

$$\dot{\rho} = \rho(r + \psi(n, b)) + V(n) + \psi(n, b) JX^* \quad [12]$$

which has solution (Horan and Fenichel, 2007)

$$\rho(t) = - \int_t^\infty [V(n) + \psi(n, b) JX^*] e^{-r(s-t) - \gamma(s-t)} ds \quad [13]$$

The implication (Reed and Heras, 1992) is that $-\rho(t)$ is the expected present value of net benefits from the current time onward, or the *ex ante* value of an optimally managed system facing the threat of invasion. This value depends on the state of the system before $V(n)$ and after an invasion $JX^*(X, a^*, h^*)$ (i.e., the severity) and the probability of invasion $\psi(n, b)$, where each in turn depends on both the ecological baseline risk of invasion and the key aspects of manager behavior – prevention, control, and adaptation. The problem is now one defined by endogenous risk.

Analytical solutions for the optimal time path of prevention are lacking although numerical solutions are available, as shown in Reed (1987). This article can glean some insight by evaluating eqn [10]. Given the interpretation of $-\rho(t)$, the implication from the maximum principle becomes apparent – prevention should be employed up until the level that balances the current marginal cost of prevention to its expected marginal benefits or the marginal welfare savings expected from a reduced risk of invasion (Horan and Fenichel, 2007). Such a prevention level is optimal unless (1) there is no probability of invasion, (2) unless prevention has no effect on the probability of invasion ($\psi = \psi_n = 0$), (3) if the invasion has minor consequences or is benign ($JX^* + \rho \rightarrow 0$), or (4) if the invasion were to improve societal welfare so that $JX^* + \rho > 0$.

From the system of eqns [10]–[12], it is possible to derive a differential equation governing the evolution of prevention. The procedure starts from time differentiating eqn [10] and substituting in the definitions provided by the initial structure of the problem and the findings from the maximum principle. To reduce the complexity, it is assumed that the present value of an optimal program of *ex post* management JX^* is time invariant from an *ex ante* perspective. The procedure allows one to determine the “key equation” governing the optimal time path of prevention (Reed, 1987)

$$\dot{n} = \frac{\psi_n(\psi + r)(V'(n) + \psi_n JX^*) + [V'(n)\psi_{nb}]\dot{b} - [V(n) + \psi JX^*]\psi_n^2}{V''(n)\psi_n - V'(n)\psi_{nn}} \quad [14]$$

Again there are no analytical solutions to eqn [14], making generalizations problematic. Numerical solutions are possible and provide some insight into the optimal prevention schedule. For example, if the analysis is restricted to consideration of time invariant levels of prevention (or $n(t) = \bar{n}$ and $\dot{n} = 0$) and if it is assumed that the background risk is constant over time so that $\dot{b} = 0$, then as it is known that $V''(n) = 0$, $\bar{n}$ can be found as the solution to

$$\psi_n(\psi + r)(V'(n) + \psi_n JX^*) - [V(n) + \psi JX^*]\psi_n^2 = 0 \quad [15]$$

To provide some illustrative insight, this expression was solved for a hypothetical collection of functions and parameters selected to be consistent with an invasion and with one another. Taking an exponential form for $\psi = e^{-c\beta(b)n}$, letting $r = 0.03$ and $B = \$1000$, restricting JX^* to being less than the value of an uninvaded state so $JX^* < B/r$, and assuming a linear form for the influence of the baseline risk of invasion $\beta(b) = a - db$ and $c = 1$, $a = 0.1$, and $d = 0.075$. For this case, a comparative static analysis of changes in fundamental

parameters on the time invariant level of prevention can be performed. Table 1 presents the description of parameters.

These comparative static effects conform to intuition. Note, however, it is uncertain whether these would hold after relaxing the restrictive assumptions. There have been few comprehensive analyses of prevention in this *ex ante* setting, although the results of the stochastic dynamic programming model in Finnoff *et al.* (2007) corroborate the results provided in Table 1. Kim *et al.* (2006) present a similar model with no differentiation in the timing of prevention and control (all decisions are made before an invasion has occurred and this uncertainty has been resolved). Although they do not focus on the timing of invasion as is done in this article, they incorporate preventative measures before and after the discovery of an invader and perform a comparative dynamic analysis on the time paths of prevention and control. The authors are able to use their model to demonstrate that if the expected damages from the invader are large enough (low JX^* in the authors' model), it is efficient to expend a larger share of resources on prevention before discovery. However, this result can be reversed if the marginal costs of this early prevention activity are sufficiently high.

Burnett *et al.* (2006, 2008) examine prevention but again in a setting that places prevention and control decisions at the same time period. Unlike the model developed here, Burnett *et al.* specify prevention by reducing repeated introduction, or reducing a flow of invaders that would otherwise create or increase an established stock. Burnett *et al.* (2008) show that the optimal prevention schedule depends on whether or not the species has established in the initial conditions of the model. If none have established, the optimal path of prevention gradually increases over a period of time to a fixed level that should be maintained into the future. If the population is already established at the start of the problem, it is then optimal to prevent at a constant level into the future (where this prevention reduces the magnitude of population growth and damage).

Ex post Management: Control

Control of an established and spreading invader has been the most well studied aspect of the problem using optimal control theory. The invasive species problem transforms a basic renewable resource problem by (typically) choosing control to maximize the negative of a discounted stream of damages and control costs. The models capture the interaction of state variables (e.g., invader abundances) and control variables

Table 1 Comparative static effects on prevention

Parameter	Description	Effect on fixed level of prevention ($\bar{n}$)
r	Discount rate	Increases in r lead to less use of prevention
b	Baseline risk of invasion	Increases in b lead to more use of prevention
B	Social benefits at risk from invasion	Greater levels of B lead to more use of prevention
c	Effectiveness of prevention	If prevention is not very effective (low c), an increase leads to more prevention. If prevention is already highly effective (high c), an increase leads to less prevention
JX^*	Present value of an optimal program of <i>ex post</i> management from time of invasion into perpetuity	Higher damages (or lower JX^*) lead to more use of prevention

(policy choices, adaptation, eradication, and control) over time and in equilibrium (steady states).

There is a long history in economics of using optimal control theory to answer related natural resource policy questions as seen in the use of the method to inform policies aimed at agricultural pests (Lichtenberg and Zilberman, 1986; Archer and Shogren, 1996; Levy and Caputo, 2008). For policies concerned with invasive species, the focus has been on the control of an invasion and whether eradication of the invader is optimal. This article illustrates the use of optimal control for managing an established invader by continuing the derivation of the value of an optimally managed system following an invasion, JX , under an assumption that the invasion occurs immediately (or $\tau = 0$). The objective functional can be written as

$$JX(X) = \max_{h,a} \int_0^{\infty} e^{-rt} VX(X,a,h,t) dt \quad [16]$$

where the strategies are control h and adaptation a , as defined in eqn [5], and the optimization is subject to the growth of the invader, as given in eqn [4]. Optimal policies for maximizing JX can be obtained by applying the maximum principle to the current value Hamiltonian (omitting time notation)

$$\mathcal{H} = B - D(X,a) - h - a + \mu(F(X) - K(h)) \quad [17]$$

where μ is the costate variable or the shadow price of the invader and signals to society the value (loss) of allowing an additional unit of the species to persist into the future. The invader as defined here results only in costs, making $\mu \leq 0$. Following the maximum principle, the necessary conditions require control and adaptation to be chosen along the optimal path to maximize the current value Hamiltonian

$$\frac{\partial \mathcal{H}}{\partial h} = -1 - \mu K_h \leq 0, \quad h \geq 0 \quad [18]$$

$$\frac{\partial \mathcal{H}}{\partial a} = -D_a - 1 \leq 0, \quad a \geq 0 \quad [19]$$

given the evolution of X follows

$$\dot{X} = F(X) - K(h), X(0) = X_0 \quad [20]$$

and the costate equation requires that μ satisfy

$$\dot{\mu} = \mu(r - F_X) + D_X \quad [21]$$

Equations [18] and [19] place restrictions on the optimal use of expenditures on control and adaptation. If control is to be used ($h > 0$), then a dollar spent on control must result in at least a dollar's "worth" of invader removals, where the marginal productivity of control expenditures K_h is valued by the shadow price μ . Similarly, if it is optimal to adapt ($a > 0$), then each dollar spent on adaptation must lower damages by at least a dollar.

Equations [18]–[21] define a system of differential equations governing the optimal evolution of the system. The solution to these systems is tricky as there is the possibility of multiple equilibria and complex transition dynamics. Furthermore, as the shadow price of the invader is negative, the problem lacks the structure typically relied upon to determine the optimality of alternative paths (Olsen and Roy, 2008; Finnoff *et al.*, 2010b).

The point is that standard sufficiency conditions can no longer be used to determine the optimality of one path and equilibrium combination in relation to another. To determine which path and equilibrium is optimal requires a comparison of the value of the entire program of management, that is, a solution-by-solution comparison of JX^* (for an elegant alternative, see Tahvonen and Salo (1996)). In most cases, analytical solutions cannot be derived and the comparisons have to be made numerically. Although the numerical solutions are dependent on the parameters and functional forms employed and so are case specific, this article has found two basic cases relating to whether or not there are repeated introductions.

The first case considers the control of an established invader that does not face the threat of repeated introductions as seen in Eiswerth and Johnson (2002) and Olsen and Roy (2008). This would be appropriate for those invasions with rare yet potentially disastrous introduction events. In this case, eqns [18]–[21] can be reduced to a pair of differential equations with a solution typically shown by the construction of a phase diagram in X and h space (ignoring adaptation) and illustrated in Figure 2. Phase diagrams are used to illustrate the optimal solution to the dynamic problem. They depict the key equilibrium points and nonequilibrium (or dynamic) directions of movement for the state and control variables. They are particularly useful in these problems as they show both the optimal paths to equilibrium points (here unique saddle paths) and the nonoptimal paths (how any pair of state and control variables would move following the small directional arrows).

The horizontal axis of the figure is the invader abundance X (with units here scaled between 0 and 1) and vertical axis expenditures on control h . The solutions to the system of eqns [18]–[21] are shown using the isoclines for X and h (trace out the combinations of X and h that keep each of the variables invariant over time) and sketches of optimal paths. The intersections of the isoclines (and the origin when the invader and control are both zero) provide the candidate equilibria for the system.

In Figure 2 there are three possible equilibrium points, a highly invaded steady state (X_H, h_H), a low invaded steady state (X_L, h_L), and an eradication steady state (0,0). The small arrows provide directions of movement in the figure, demonstrating the conditional stability of both the eradication and the highly invaded equilibrium points and the instability of the low invaded equilibrium point. Which (of the stable) equilibrium points are optimal depends (for a given set of circumstances) on the initial conditions in relation to a Skiba point in the neighborhood of the unstable equilibrium point (X_L, h_L). If the invasion is detected before the invader population has risen to X_L , it will be optimal to control to eradication. If the invasion is detected in its moderate or latter stages (i.e., an abundance above X_L), it is optimal to control the invader to maintain a heavily invaded equilibrium. In relation to the model of prevention discussed earlier (i.e., eqn 7), the optimized value function JX^* for early detection and eradication is always higher than moderate and late detection that leads to maintenance at X_H (although which equilibrium is optimal depends on the initial conditions).

The exact location of the equilibrium points and optimal path(s) depends on the specifics of a problem. A key ecological variable is the rate of spread or growth of the invader. In comparison to the situation depicted in Figure 2, a species

Figure 2 Phase diagram for control of an established invader without reintroduction.

Figure 3 Phase diagram for control of an established invader with reintroduction.

with a lower rate of spread (or intrinsic growth) would have a lower X isocline and a higher h isocline. This makes eradication optimal over a wider range of initial conditions. If the spread rate or growth rate of the species is higher, the opposite occurs – eradication is now optimal over a narrower window of initial conditions. Key economic variables are the economic damage of the invasion, the discount rate, and the marginal cost of control. Greater damages (lower discount rate and lower marginal costs of control) raise the h isocline, leading to an increase in the range of initial conditions over which eradication is optimal and lowering the highly invaded steady state. Lower damages (higher discount rate and higher costs of control) in turn lower the h isocline, reducing the interval of initial conditions for eradication and increasing the highly invaded steady state.

The second case considers situations of repeated introductions, as considered by [Burnett et al. \(2008\)](#) and [Finnoff et al. \(2011\)](#). This is appropriate for invasions with numerous entry pathways. Now the phase space and isoclines undergo modification due to the inclusion of repeated introductions. The main implication is the isocline for X no longer intersects the origin. This indicates that through repeated introductions and a high positive amount of growth at low invader abundances, the invader will soon be established. [Figure 3](#) presents a sketch of one potential configuration of the phase space with all labeling consistent with [Figure 2](#).

As [Figure 3](#) illustrates, a completely eradicated equilibrium does not exist for invasions with repeated introductions (i.e., perfect prevention is impossible). There are three equilibrium points, consisting of a slightly invaded equilibrium (X_L, h_L), a

moderately invaded equilibrium (X_M, h_M) , and a highly invaded equilibrium (X_H, h_H) . The slightly and highly invaded equilibria are conditionally stable (saddle points); the moderate equilibrium is again unstable. Repeated introductions imply that a one-time eradication program is insufficient; even if the invader can be held in check at a low abundance, it will have to be consistently maintained over time through a persistent high application of control.

The optimality of the slightly invaded steady state in relation to the highly invaded steady state again depends on the relationship between the initial conditions and the moderately invaded equilibrium point. Invasions detected early enough so their initial conditions are less than the moderately invaded equilibrium point should be optimally directed to the slightly invaded equilibrium (with high JX^*). Invasions detected later in their progression should be managed to the highly invaded steady state (with low JX^*). Variations in key parameters shift the isoclines in a similar fashion, as documented in Finnoff *et al.* (2010b). Across their set of key parameters, Finnoff *et al.* demonstrate that the control of the invasion process to the slightly invaded steady state is optimal for early detection and relatively high damages, low rates of density-dependent spread, and low rates of repeated introductions. Invasions that should be controlled to the highly invaded steady state are those detected in their latter stages with low relative damages, high rates of repeated introductions, and high levels of uncertainty in species location.

Concluding Comments

This article has reviewed the insight that optimal control theory can provide for the bioeconomics of invasive species policy. The key message is that a bioeconomics framework can provide useful insight into cost-effective invasive species management. People invest scarce resources to prevent and control the risks invasive species pose to ecological and economic systems. Just how people invest and how they *ought to* depend on what they know about the economic and biological underpinnings of the problem and how the systems respond to one another. Here the authors have used the idea of endogenous risk in an optimal control setting to frame the question of how to best manage the prevention and control of invasive species. The approach is inclusive and accounts for uncertainty, both biological and economic circumstances of invasions, and interdependent systems.

The dynamic endogenous risk framework provides a means to evaluate the trade-offs at the foundation of designing and implementing policies directed at invasive species. Creating scenarios that capture realistic trade-offs still requires more information on the economic and ecological systems, and the critical feedback loops between the two systems. More modeling and data collection is needed. As better insight is gained into understanding the alternative risk reduction strategies, it is more likely to understand the degree to which prevention has been underfunded (Leung *et al.*, 2002).

The authors appreciate the limits of their approach. The optimal control framework is well suited for control actions that can be continuously adjusted such as pesticide/herbicide application or biomass removal. The existing optimal control

literature has found that more aggressive control actions of this type are optimal early in the invasion process when the costs of such actions are relatively low (e.g., Olson and Roy, 2002). But for the control of invasive species at the state and federal levels, control actions are delayed with less aggressive actions initially implemented. These broad-scale state- and federal-level policies require significant economic commitments that are typically difficult to adjust over time. Examples include decisions to “blacklist” potentially invasive species, the construction of an electric barrier in the Chicago Ship and Sanitary Canal to prevent Asian carp spread into the Great Lakes, and the mandatory ballast water-exchange policy for ocean-going shipping. For broad-scale control decisions, alternative approaches such as an optimal stopping framework could be considered (Neher, 1990).

The goal is to understand better the consequences of invasion and the policies that can alleviate these consequences. And although more is known now than a decade ago about the bioeconomics of invasive species, more work is needed on the *economic welfare* consequences of invasions and of associated public policies. This will require more realistic economic parameter assumptions and accounts of ecological thresholds in the authors’ models.

Appendix A

For the derivation of J: The following is based on Rick Horan’s implementation of the Reed and Heras method. Let the random variable denoting the time of invasion be given by Z , for some time horizon T . If $Z = T$, no invasion occurs. As the time of invasion is a random variable, so is the present value of rewards

$$\begin{cases} \int_0^Z V(n,t)e^{-rt} dt + e^{-rZ}JX^*(X(Z)) & \text{if } Z < T \\ \int_0^T V(n,t)e^{-rt} dt + e^{-rT}JX^*(X(T)) & \text{if } Z = T \end{cases} \quad [A1]$$

The cumulative distribution function (cdf) of Z is $(1-S_p(z))$ for $z < T$ and 1 for $z \geq T$. This allows one to write the expected present value of rewards as

$$\begin{aligned} J = & \int_0^T \int_0^Z V(n,t)e^{-rt} dt d(-S_p(Z)) \\ & + \int_0^T e^{-rZ}JX^*(X(Z))d(-S_p(z)) \\ & + S_p(T) \int_0^Z V(n,t)e^{-rt} dt + S_p(T)e^{-rT}\psi(n(T),b(T)) \end{aligned} \quad [A2]$$

Let the first term in eqn [A2] be given by J^1

$$J^1 = \int_0^T \int_0^Z V(n,t)e^{-rt} dt d(-S_p(z)) \quad [A3]$$

As $d(-S_p(z)) = d\left(-e^{-\int_0^z \psi(n(t),b(t)) dt}\right) = S_p(z)\psi(n(z),b(z)) dz$, eqn [A3] can be simplified to

$$J^1 = \int_0^T \int_0^Z V(n,t)e^{-rt} S_p(z)\psi(n(z),b(z)) dt dz \quad [A4]$$

The integration can be simplified by switching the order of the integrals in eqn [A4]. Noting the limits of z for a given t

will be $t \leq z \leq T$ and time ranges from $0 \leq t \leq T$ finds

$$\begin{aligned} J^1 &= \int_0^T \int_t^T V(n,t) e^{-rt} S_p(z) \psi(n(z), b(z)) dz dt \\ &= \int_0^T V(n,t) E^{-rt} S_p(T) \int_0^T V(n,t) e^{-rt} dt \quad [A5] \end{aligned}$$

Let the second term in eqn [A2] be given by J^2 , make the same substitution for the cdf as in the earlier equation, and change the dummy variable of integration

$$J^2 = \int_0^T e^{-rt} JX^*(X(t)) S_p(t) \psi(n(t), b(t)) dt \quad [A6]$$

Substituting eqns [A5] and [A6] into eqn [A2] finds

$$\begin{aligned} J &= \int_0^T [V(n,t) + \psi(n(t), b(t)) JX^*(X(t))] e^{-rt} S_p(t) dt \\ &\quad + S_p(T) e^{-rT} \psi(n(T), b(T)) \quad [A7] \end{aligned}$$

To push the time horizon T to infinity, take the limit as $T \rightarrow \infty$, and as it is known that $S_p(t) = e^{-\gamma(t)}$, eqn [A7] simplifies to

$$J = \int_0^\infty [V(n,t) + \psi(n(t), b(t)) JX^*(X(t))] e^{-\gamma(t)} dt \quad [A8]$$

where the change of variables allows $\dot{\gamma} = \psi(n, b)$, $\gamma(0) = 0$ so that $S_p(0) = 1$.

For the derivation of ρ :

From the current value Hamiltonian

$$H = e^{-\gamma} (V(n) + \psi(n, b) JX^*) + \mu \psi(n, b)$$

the first-order necessary condition of the maximum principle can be derived

$$\frac{\partial H}{\partial n} = e^{-\gamma} (V'(n) + \psi_n JX^* + \mu \psi_n) \leq 0$$

and also the equation of motion for the current value costate variable (shadow price)

$$\begin{aligned} \dot{\mu} &= r\mu - \frac{\partial H}{\partial \gamma} = r\mu - \frac{\partial (e^{-\gamma} (V(n) + \psi(n, b) JX^*) + \mu \psi(n, b))}{\partial \gamma} \\ &= r\mu + e^{-\gamma} (V(n) + \psi(n, b) JX^*) \end{aligned}$$

If one defines $\rho = e^{\gamma} \mu$, then the conditional current value Hamiltonian is $\bar{H} = H e^{\gamma}$. One can then time differentiate ρ to find $\dot{\rho} = \dot{\mu} e^{\gamma} + \dot{\gamma} \mu = e^{\gamma} (\dot{\mu} + \dot{\gamma} \mu) = e^{\gamma} (r\mu + e^{-\gamma} (V(n) + \psi(n, b) JX^*) + \psi(n, b) \mu)$, which, given the definition of $\rho = e^{\gamma} \mu$, can be written as

$$\begin{aligned} \dot{\rho} &= (r\rho + V(n) + \psi(n, b) JX^* + \rho \psi(n, b)) \\ &= \rho(r + \psi(n, b)) + V(n) + \psi(n, b) JX^* \end{aligned}$$

To determine the key equation, the authors time differentiate the interior solution for the first-order condition, rearrange terms, and resubstitute from the maximum principle

$$\dot{n} = \frac{\psi_n(\psi + r)(V'(n) + \psi_n JX^*) + [V'(n) \psi_{nb}] \dot{b} - [V(n) + \psi JX^*] \psi_n^2}{V''(n) \psi_n - V'(n) \psi_{nn}}$$

Glossary

Consumer surplus Value to people of large amounts of goods or services minus the cost of creating them.

Marginal value Additional value of adding or subtracting one unit of a good or service.

Productive benefits Values that are bought and sold in markets such as honey and timber or which

enhance goods and services sold in markets such as real estate.

Valuation Practice of measuring the economic values that people have for a good or service.

Willingness to pay Highest payment a person would make in return for a good or service.

Introduction

There has been a great deal of confusion and controversy surrounding the valuation of biodiversity. Part of the confusion lies in understanding the nature of economic value and the relationship between an individual's values and society's values. Part of the confusion lies with the different definitions of the term "biodiversity" and part of it lies with the different methods employed to value biodiversity.

Economic value is a fundamentally anthropocentric concept representing the trade-off, that the people are willing to make amongst valuable outcomes. How much income would a particular person give up to get something of value such as an additional deer or an additional pair of bald eagles nearby? Economic values reflect the benefits each person feels they receive from a specific change in the environment. Economics does not judge whether these individual benefits should be high or low. Economics simply measures the values people have.

Biodiversity benefits many people, not just a single person. The social value of biodiversity is the sum of the individual values of all the people who benefit from that biodiversity. Economic studies reveal that individual values vary a great deal across the population, especially in a heterogeneous society. There is not a single individual value for biodiversity but rather a distribution of individual values. However, the social value, the sum of all these individual values, is a single number. This makes social values controversial. Someone with high personal values for biodiversity may feel that the social value is not high enough. In contrast, someone with low personal values for biodiversity may feel that the social value is far too high. Social values are not intended to reflect a single person's values. They are supposed to reflect the values of the entire society.

Environmental protection cannot provide the exact amount of biodiversity that each person wants because only one level of biodiversity can be provided in each location. People who place a high individual value on biodiversity are often frustrated that not enough is being done, while at the same time people who place a low value on biodiversity, often feel too much is being done to protect biodiversity. This problem is not unique to biodiversity, it is a common problem

of all shared or public goods. But it is one of the reasons why biodiversity values are so controversial.

Social values for biodiversity help resource managers determine what trade-offs society wants to make across the many services that are possible. For example, society must choose between having more food (farms), more timber products (managed forests), or having more wildlife (natural lands). Even within natural lands, society must choose between allocating land for species that prefer complete forest cover, a mix of forest cover and openings, or open spaces. Valuation guides how to choose across the many different possible outcomes. Valuation is a key component of resource management and it is intended to guide actual management decisions.

Note that valuation extends beyond just goods and services traded in markets. It also includes nonmarket goods and services as well. Although the prices of market goods are readily observable in most circumstances, the marginal value of nonmarket goods and services are generally more difficult to measure. In fact, some nonmarket services may not be possible to measure at all, such as nonuse values.

The term 'biodiversity' is defined differently depending on the policy issue at hand. Sometimes it is meant to reflect species richness or the number of species in a particular location. Sometimes it is meant to capture the existence of an animal that might be eliminated entirely (endangered species). Sometimes biodiversity is defined as an entire ecosystem. Biodiversity sometimes simply reflects the abundance of a particular animal even if that animal is common (starlings, rabbits, or deer). The multiple meanings of biodiversity are a source of confusion and cloud what is meant by the value of biodiversity. In this essay, the authors consequently try to be as specific as possible about what is being valued and try to avoid valuing 'biodiversity' *per se*.

It is important to understand that valuation is context-specific. There is no single value for a maple tree, a wetland, or a coral reef. The value of a particular ecosystem, species, or individual depends on the circumstances surrounding it, including its relative scarcity and the tastes, number and income level of the people placing a value on it. As natural areas or populations become scarce, each remaining area and animal

becomes more valuable. A single maple tree is going to be quite common and therefore of low value in the middle of a maple forest, but it may be very special and of high value in a city park where it is the only one. An acre of wetland may be highly valued in the middle of a dense metropolitan area where it provides scarce habitat and open space but it may have very low value in an immense, remote river delta. A Minnesota resident may value a whooping crane near their home more than a different, though possibly rarer, crane in distant Russia. A small natural park will have more value in a dense urban setting than in a rural area simply because more people are nearby to value it. Finally, richer people can afford to give up more income (have higher values) for a specific type of biodiversity than poorer people solely because they have more money.

The fact that biodiversity values are context-specific suggests to researchers that they should not be seeking a single number to measure the value of biodiversity. Valuation studies should focus on measuring specific values for biodiversity in specific circumstances as precisely as they can. This allows policymakers to evaluate the consequences of concrete management decisions.

Valuation of Productive Benefits

The marginal values of biodiversity traded in markets are readily observable as market prices. For example, crops grown on farmland, animals raised on pasture, and trees harvested for timber are all traded in markets and have readily observable prices (marginal values). The nonmarginal values of large changes in these goods can be estimated from market data as well, using consumer surplus. Consumer surplus is the area underneath the demand function minus the cost. It captures the fact that prices increase (decrease) if there is a large decrease (increase) in the quantity of the goods supplied.

Although market prices are generally widely available, there are some circumstances where they might be difficult to observe. For example, the prices of many nontimber forest products (NTFP) collected in remote locations may not be easily observed. Careful market studies of the collection of NTFPs from specific forestland can help address these shortcomings.

Many of the market values for biodiversity are actually inputs into production. Although crops, timber, and livestock are readily recognized as goods bought by consumers, the value paid at a store is much higher than the price paid to farmers and forest owners at their farm gate. The price in the store often involves processing, spoilage, transportation, and presentation. Although these costs are reflected in the final price to consumers and must be subtracted to get the price paid to the resource owner. A more obscure use of biodiversity is an input that occurs with research and development (R&D). Biodiversity is a source of breeding material and new pharmaceuticals (Simpson *et al.*, 1996). However, the process of finding new species and drugs is very expensive and involves many other inputs, so that the contribution of biodiversity is generally low. Markets place an especially low value on R&D values because any sample of a plant or animal contains all the valuable information of that species. It is also true that many species share common characteristics that are of value to R&D so that each

single species has a small probability that it alone can contribute a valuable gene or compound.

The marginal value of biodiversity services that are not traded in markets are not as readily observed. For example, Yosemite National Park, a local city park, a flock of geese, old-growth (primary) forests, or the remaining spotted owls are not traded in markets. Without market trading, there is no price for these goods and services. However, that does not imply they have no value. People may value these nonmarket goods and services because they contribute to their quality of life, even if they do not contribute to the economy.

There are many methods to measure the nonmarket values of biodiversity (Bockstael *et al.*, 2000; Freeman, 2003; Haab and McConnell, 2003; Mendelsohn and Olmstead, 2009). But it is critical that users of estimated values of nonmarket goods and services understand the strengths and weaknesses of these methods as some methods are far more reliable and accurate than others.

Sometimes, the value of biodiversity can be inferred from the costs its presence avoids. For example, certain watersheds in the Catskill mountains are dedicated to providing the water supply of New York city (Chichilnisky and Heal, 1998). Buying more land for watershed protection reduces the cost of water treatment plants. The reduced water treatment cost for New York city is estimated to be worth \$6–8 billion whereas the cost of setting aside the additional land is estimated to be just \$1–1.5 billion (Chichilnisky and Heal, 1998).

Some species or resources have indirect values. They are not used or appreciated directly by people but they are an important component of an ecosystem that generates final ecosystem goods and services. For example, people might not actively use fungus, bacteria, and worms but they provide a valuable ecosystem function by breaking down decaying plant material. These indirect values can be estimated using a production function approach. Inputs to the ecosystem production function can be valued from their contribution to output. Of course, one cannot add these input values to output values because that would be double counting. But one can argue that without these inputs, the outputs would be reduced. Society should protect these inputs in order to protect the output.

In practice, the production function approach is sometimes misused. Studies should measure the value of output in terms of the net value that the output generates. Unfortunately, many studies rely on the gross revenues (price times quantity) of outputs and forget to subtract other costs needed to obtain the output. The most grievous example of this concerns fisheries. An efficient fishery requires substantial resources to catch the fish (boats and fishermen). These costs must be subtracted from the gross revenue of the fish caught to measure the net rent of the fishery. In the frequent case of a common property fishery, there is an excess amount of fishing effort applied in each fishery. Quite often, the cost of harvesting the fish is equal to gross revenue. There is no net revenue in this case. If the fishery were lost, the lost fish would be equal in value to the regained inputs that now could be used for some other purpose. The fishery has zero net value. Any resource required to promote that fishery such as mangroves has zero value as well.

Another critical element of valuation is whether one is valuing a small change or a very large one. Small changes tend not to affect marginal values (prices) but large changes will. For example, if one were to damage a single fishery, the global price of fish would not be affected. The loss can be measured in terms of the current price of fish. However, if one were to damage all the world's fisheries, fish would become scarce and the price or marginal value of fish would change. Large reductions (increases) in supply can lead to large increases (reductions) in price or marginal value. With large scale changes, it is necessary to take these price changes into account using consumer surplus. However, when valuing small changes, it is just as important not to include price changes (consumer surplus).

Valuation of Recreational and Aesthetic Benefits

There are also several methods for valuing the recreational benefits of biodiversity. For example, the travel cost method can measure the recreational value of specific sites. Travel cost methods also have been used to measure the recreational value of special biodiversity 'hotspots', such as the Galapagos Islands, Costa Rica's Monteverde Cloud Forest, and the Great Barrier Reef.

However, much less progress has been made measuring the value of specific characteristics of ecosystems. Resource managers of conserved sites thus have little insight into how to manage their lands to provide the greatest biodiversity benefits. Should natural lands be left untended or would these lands provide more value if protected from fire? Should land managers cut trees to create openings for wildlife or leave entirely intact forest canopies? Should the populations of certain wildlife be actively reduced or increased to favor other species?

There are several techniques that value site characteristics: discrete-choice, random utility travel cost models; hedonic travel cost methods; and stated preference methods, including choice experiments and contingent ranking (Bockstael *et al.*, 2000; Brown and Mendelsohn, 1984; Mendelsohn and Olmstead, 2009). For example, hedonic travel cost methods have been used to value old growth, forest species along backcountry trails, deer, and sport fishing populations of trout. Discrete-choice random utility models have valued the quality and number of fish species, the abundance of pheasants in wetlands, deer on agricultural lands, and the 'environmental diversity' of forested areas. Choice experiments have been used to value changes in the quality of coral reef ecosystems in the Caribbean (Hanemann, 1984).

Hedonic property studies can also capture the value of biodiversity when it provides local recreational or aesthetic benefits for which proximity is important. For example, waterfront, nearby parks, and invasive aquatic species all affect the value of nearby property. By examining how property values are affected, one can value these attributes.

Another controversial technique used in the literature is to value ecological services by the cost of substitute services. For example, a tree in New York city provides shade and therefore some cooling. The substitute technique is controversial because many studies do not use an appropriate substitute.

For example, one study assumed that air conditioning is a close substitute for a tree. The tree is worth the reduced air conditioning cost. However, a more appropriate choice is a parasol. The tree is worth the cost of a parasol to people underneath the tree.

One lesson with respect to all of these valuation methods is that it is important not to double count the same value. Recreation values can be measured by several of these techniques. The recreational values also reflect aesthetic values and they are related to preferences for genetic diversity. Using multiple valuation methods to capture these values helps to confirm that the values are robust. However, adding them together may be counting the same thing twice.

Valuation of Nonuse Benefits

The most controversial set of values for biodiversity concerns nonuse values. By definition, nonuse values involve no contact between the person with the value and the environment being valued. They are strictly conceptual values. Whether the site or species continues to exist or not is really not known or directly experienced by the person. Some people argue that such 'existence values' should be included as one component of biodiversity values (Portney, 1994). Unfortunately, it is not possible to reliably measure nonuse values (Diamond and Hausman, 1994). There is no behavior to examine to see what people are actually doing to appreciate the resource since people have no contact with the resource. Stated preference methods for existence values are subjected to substantial errors and biases since people often have no experience with, or knowledge of the site or species in question. Respondents' stated values cannot grasp the scale or scope of the resource. For example, people respond with the same value to protect 1000, 10,000, or 100,000 birds in a remote flyway.

Conceptually, it is not clear that existence values can be very large. If one had to pay for the existence of each unit of biodiversity on earth, what would be the aggregate payment? Divide that payment into specific amounts for specific resources and the existence value for each resource becomes quite small. Further, people will also pay for the existence of jobs, managed or developed sites, and prosperity. The net existence value for conservation may not be as large as some people would think.

The policy and management implications of existence value are also unclear. High existence values imply that society should avoid total destruction of a species, but they may not have any relevance for most management decisions that do not permanently eliminate species.

Other Valuation Approaches

Valuation studies are expensive and so some researchers have attempted to interpolate between careful site-specific valuation studies to determine overarching values for species not included and for areas not measured. Such 'meta-analyses' are only as good as their assumptions. Interpolation can be made across a number of sites that are alike. Housing appraisers value a house not for sale by looking at the market values of

similar homes that have been sold in the market. However, if care is not taken in selecting representative sites, the studies can be biased. For example, the values of ordinary sites cannot be inferred by looking at the estimated values of the most popular destinations. Since researchers tend to value the most popular, most valuable, and most accessible sites first, there is a real danger that meta-analysis will overestimate the value of the remote and rarely visited places that have been overlooked.

Ecological models measure the productivity of ecosystems using Net Primary Production (NPP). Sites with higher NPP tend to grow faster. For example, a timber forest with high NPP also has high growth rates for timber. Farms with higher NPP produce more crops. Managed systems with higher NPP are generally more valuable. However, unmanaged natural ecosystems with higher NPP do not necessarily have more value. People rarely value natural areas by how quickly trees, plants, and animals grow. They are more interested in the state of the forest. So NPP can lead to unrealistic rankings of ecosystem values. For example, NPP rankings suggest that marine systems on continental shelves are worth more than terrestrial ecosystems, and wetlands are by far the most valuable terrestrial ecosystem. However, natural systems produce many plants and animals that have little value and may even be a nuisance. So measuring NPP without making any distinction as to whether a plant or animal is desired has little significance.

The valuation of biodiversity has come a long way over the past few decades. There are now more methods to value ecosystems than ever before and there are more places that have been valued. However, the valuation of biodiversity is not at all complete. There remains a pressing need for more valuation studies of ecosystem characteristics so resource managers

can begin to manage conserved areas for their highest and best use.

Glossary

Agrobiodiversity The variety and variability of living organisms that contribute to food and agriculture in the broadest sense, and that are associated with cultivating crops and rearing animals within ecological complexes. It is further expanded in some contexts to include all the organisms present in an agricultural landscape. Examples consist of crops and animal breeds, their wild relatives, and the species that interact with and support these species.

Direct use value The economic value derived from direct use or interaction with a biological resource or resource system.

Ex situ conservation A conservation method that entails the removal of germplasm resources (seed, pollen, sperm, and individual organisms) from their original habitat or natural environment with the aim to keeping components of biodiversity alive outside their original habitat or natural environment. It includes gene bank storage (seed and field), *in vitro* storage, pollen storage, and DNA storage. Seed gene banks are the most common storage practice. In the case of plant breeding it generally involves the collection, classification, evaluation, and utilization of agrobiodiversity.

In situ conservation A conservation method that attempts to preserve the genetic integrity of gene resources by conserving them within the evolutionary dynamic ecosystems of the original habitat and seeks to maintain and recover viable populations of species in their natural surroundings. It is also known as on-farm conservation, which encourages farmers to continue selection and management of local crop populations.

Indirect use value The economic value associated with the services supported by a resource as opposed to the actual use of the resource itself.

Landrace A local variety of a domesticated animal or plant species that has developed largely by natural processes, by adaptation to the natural and cultural local environment. The term traditional variety is sometimes applied to plant landraces.

Market value chain It describes the sequence of activities from producing raw material and transforming the same into products that can be purchased by final consumers. It can be used as a strategy to create incentives to farmers to conserve landraces with traits that are valued by consumers. It is based on interlinked value-adding activities that convert landraces as inputs into marketable outputs which, in turn, add to competitive advantage.

Natural insurance value It is associated with the value of biodiversity in terms of reducing risk to its users and can be more or less substitutable for financial insurance.

Option value The potential benefits of a resource not derived from actual use and expresses the preference for the conservation of such resource against some probability that it can be used at some later date.

Payments for agrobiodiversity conservation services A variant of the term payments for ecosystem services and used in the context of agrobiodiversity.

Plant genetic resources for food and agriculture Any genetic material of plant origin of actual or potential value for food and agriculture. Its diversity embodies the diversity among cultivated species or interspecific diversity and the diversity within species, i.e., the variation of populations belonging to one species, or infraspecific diversity.

Plant species A group of organisms capable of interbreeding freely with each other, but not with members of other species. In taxonomic classification, a subdivision of a genus; a group of closely related individuals descended from the same stock.

Plant variety A subdivision of a plant species. An agricultural variety is a group of similar plants that by structural features and performance can be identified from other varieties within the same species. Synonymous with cultivar.

Underutilized varieties It is also known as neglected varieties and refer to those species with under-exploited potential for contributing to food security, health (nutritional/medicinal), income generation, and environmental services.

Introduction

The economics of agrobiodiversity deal with the causes and implications of changes in biological diversity in agricultural landscapes. Agrobiodiversity is a key asset that sustains food production systems worldwide and provides cultural as well as aesthetic values for society (Jackson *et al.*, 2007a). One type of reasonably well-understood agrobiodiversity is the

domesticated or “planned diversity,” which is associated with the genetic diversity of cultivars and breeds. This is the basis of local as well as global food supply and nutrition in both subsistence-based societies and technologically advanced societies. However, today, only about 30 plant species out of the global agricultural biodiversity are used to meet 95% of the world’s food energy needs (FAO, 1998) and it is estimated that the total global food supply is provided on average by just 100

species (Will, 2008). It is also estimated that more than 1.4 billion people live in farm households that critically depend on local plant genetic resources (Brush, 2000). In fact, smallholder farmers in the developing world continue to maintain the majority of such remaining agrobiodiversity (Wale *et al.*, 2010). The value of this agrobiodiversity extends far beyond the livelihoods of smallholder farmers, however, since it forms the basis of all plant breeding programs for stress tolerance and pest resistance (e.g., Reynolds *et al.*, 2007; FAO, 2010; Varshney *et al.*, 2010), and of much current work to exploit genetic resources via molecular methods (Varshney *et al.*, 2009). The narrow agricultural portfolio of present day's agriculture raises the important question of how effectively major crops alone can contribute toward food security, poverty reduction, and the continued delivery of valuable ecosystem services in agricultural landscapes (Figure 1).

Within such planned diversity, we focus on the diversity of plant genetic resources relevant for food and agriculture. Plant genetic resources for food and agriculture (PGRFA) diversity have two main dimensions: (1) the diversity among cultivated species or interspecific diversity; and (2) the diversity within species, i.e., the variation of populations belonging to one species (intraspecific diversity). Both types depend on the underlying genetic diversity present within and among cultivated species, and the evolutionary processes of human selection within agroecosystems (Bellon, 2009). Since the Neolithic revolution 10,000 years ago, humans have managed the diversity of crops and livestock through selection, experimentation, innovation, and exchange. Modern crops are the result of thousands of years of such evolutionary processes (Brush, 2000). Most of the crop genetic diversity used

historically (and easily available to humans) is contained in landraces of both major and minor crops. Landraces are well-adapted to local environmental conditions and have the capacity to tolerate biotic and abiotic stress, resulting in high yield stability partly because they are typically genetically diverse (Villa *et al.*, 2006). They often produce an intermediate yield level under a low-input agricultural system that depends on a set of farmers' practices of seed selection, field management, as well as a local knowledge base (Bellon, 2009).

Local varieties or landraces can be conceptualized as "open, dynamic and decentralized genetic systems since they are the crop populations that farmers manage, and which result from farmers' seed selection practices, the flows of seed among them, and farmers' production and utilization strategies" (Bellon, 2009: p. 54). Clonal propagation of genetic material (such as for agroforestry trees) often requires grafting and budding practices, which somewhat constrains farmer selection and utilization, and thus may be more successful via participatory domestication and community partnerships (Leakey, 2012).

A variety of scientific disciplinary fields have contributed to our understanding of the functions of planned agrobiodiversity (Smale *et al.*, 2001). Examples from the natural sciences include the agricultural sciences, and their pursuit of a better understanding of how to manage crop breeding for enhancing agricultural productivity and food security (e.g., Cooper *et al.*, 2001; Leakey, 2012), and to promote sustainable agriculture more generally through its ecological functions (e.g., Swift *et al.*, 2004; Jarvis *et al.*, 2011). The cultural role of agrobiodiversity is often stressed by ecological and agricultural

Figure 1 Regions of diversity of major cultivated plants. Reproduced from FAO (1998) *The State of the World's Plant Genetic Resources for Food and Agriculture*. Rome, Italy: Food and Agriculture Organization of the UN, and adapted by IDRI, http://web.idrc.ca/en/ev-30549-201-1-DO_TOPIC.html

anthropology (e.g., Brush, 2004; Veleto and Skarbø, 2009) and human ecology (e.g., Dumaesq *et al.*, 2010; Stromberg *et al.*, 2010) and questions about its governance is addressed by political science (e.g., Andersen, 2008; Sperling *et al.*, 2008; Moore). Economics focuses on the causes and consequences of biodiversity loss in general, and agrobiodiversity loss in particular society (Perrings, 2001). Ecological economics as transdisciplinary field is well located to pursue an integrated effort to understand the complexity behind crop agrobiodiversity benefits and its role in supporting human well-being. For other types of agrobiodiversity (e.g., wild plants, soil biota, or arthropods) at the community and landscape level, knowledge is more scattered because inventories and functions are so much more difficult to assess (Jackson *et al.*, 2009).

Despite the importance of agrobiodiversity in contributing to the sustainability of agricultural practices, many plant and animal genetic resources are increasingly being lost from agricultural landscapes worldwide (Perrings *et al.*, 2006; Hajjar *et al.*, 2008). Additionally, as a direct result of growing commercialization and industrialization of farming systems (e.g., via the “Green Revolution”) agroecosystems are increasingly characterized by high levels of intensification with low levels of agrobiodiversity (Thrupp, 2000; Jackson *et al.*, 2007b; Tschamtkke *et al.*, 2012). It is estimated that humans have made use of about 7000 plant species (FAO, 1998). According to a comprehensive FAO assessment of the state of the world’s animal and plant genetic resources, out of 7600 livestock breeds, 20% are classified as being at risk, and 9% are already extinct. Most of these are located in developing countries where the risk of loss is highest, and between 2000 and 2006 alone 62 breeds became extinct (FAO, 2007a, 2009). Illustrative examples are those of Mexico and China where since the 1930s, 90% of all local maize varieties and 80% of all local wheat varieties have been lost, respectively (FAO, 1997). The 2010 FAO follow-up report explicitly noted that the threats to diversity are intensifying, partly due to climate change (Ceccarelli *et al.*, 2010; FAO, 2010).

Off-farm, *ex situ* gene bank facilities store growing collections of germplasm of local crop varieties and wild relatives (FAO, 2010). These *ex situ* facilities provide a relatively low-cost method of safeguarding genetic resource material in the state it was collected, avoiding loss or degeneration (Hawkes, 1983; Plucknett *et al.*, 1987; Brush, 2004), and are considered key to the protection of genetic diversity in the face of climate change (Ceccarelli *et al.*, 2010; FAO, 2010). Accessions in gene banks are used mainly for crop breeding programs by scientists and farmers (Smale and Day-Rubenstein, 2002; Hodgkin *et al.*, 2003). The total number of accessions conserved *ex situ* in the world is 7.4 million, from which it is estimated that less than 30% are distinct, i.e., between 1.9 and 2.2 million (FAO, 2010). But even if the world’s major crops are found in *ex situ* facilities, many minor crops and crop wild relatives that are a key asset for the livelihoods of the rural poor worldwide are underrepresented in such gene-banks (Padulosi *et al.*, 2002). Moreover, agrobiodiversity conservation is inherently a dynamic process requiring ecological relationships such as gene flow between different populations and species, coevolutionary adaptation and selection to predation and disease, and systems of agricultural knowledge and practice

associated with genetic diversity, which cannot be achieved *ex situ* (Altieri and Merrick, 1987; Wood and Lenne, 1997; Brush, 2004).

On-farm or *in situ* agrobiodiversity conservation is based on the maintenance of crop diversity by farmers themselves. It involves management of local crop populations including the maintenance of their evolutionary processes of natural and human selection based on traditional knowledge, seed saving, and exchange (Bellon *et al.*, 2009). *In situ* and *ex situ* agrobiodiversity conservation can be seen as complementary strategies. The former maintains a stock of genetic diversity in continuous evolution and provides commercial and crop breeder programs with valuable genetic material for innovation (Brush, 2000).

Based on knowledge of the role of agrobiodiversity, stemming from research conducted in the last couple of decades, increasing emphasis is being put on biodiversity-based paradigms for sustainable agriculture (Collins and Qualset, 1999; MEA, 2005; Letourneau *et al.*, 2011), both as potential solutions to the many problems associated with intensive agricultural practices and to generate greater resilience to food systems (Jackson *et al.*, 2007a,b). More specifically, agrobiodiversity is viewed as a means of survival for the world’s rural poor (Smale, 2006) and as a mechanism for buffering against output losses due to pests and diseases in traditional as well as commercialized agricultural systems (Heisey *et al.*, 1997). It also serves as a key input into locally sustainable cropping (Bellon *et al.*, 1997) indigenous technology systems. More globally it serves as a repository of valuable traits that can help satisfy the evolving tastes and preferences of consumers (Evenson *et al.*, 1998) and allow future genetic improvements on which the global supply of food products depends (Koo *et al.*, 2004).

The challenge is threefold: (1) to better understand the drivers of agrobiodiversity change; (2) to enhance the knowledge of the intertwined ecological and social functions of agrobiodiversity by determining its contribution to ecosystem services and their economic value; and (3) to evaluate alternative options for the sustainable use and conservation of agrobiodiversity on-farm, where the latter implies “the combined set of actions (and policies) by which a sample, or the whole, of a plant/animal population is subjected to processes of genetic and/or environmental manipulation with the aim of sustaining, utilizing, restoring, enhancing and understanding (characterizing) the quality and/or quantity of the genetic resources and its products” (Drucker and Smale, 2007: p. 623).

Economics is well suited to studying the drivers of agrobiodiversity change, to linking agrobiodiversity with ecosystem service values, and to devising instruments for its sustainable conservation and utilization in agricultural landscapes. In what follows, the economics of agrobiodiversity is reviewed where the latter refers to planned (domesticated) plant and animal genetic diversity and its conservation refers to the *in situ* or on-farm approach. The next section describes the problem of agrobiodiversity loss, its economic drivers, and the role of Agrobiodiversity in supporting economic development. The section The Value of Agrobiodiversity addresses the different types of economic value associated with agrobiodiversity and ways to estimate them in order to

demonstrate its social worth as natural capital. The section Economic Instruments for Agrobiodiversity Conservation focuses on the economic instruments that can be used to capture and share the social value by farmers generated through their on-farm conservation effort.

The Economic Problem of Agrobiodiversity Loss

As with the management of biodiversity in general, changes in agrobiodiversity is seen in economics as an investment/disinvestment decision (Swanson, 1998) made in the context of evolving sets of preferences, “value systems,” moral strictures, information, technological possibilities, and social, cultural, and institutional conditions (Pascual and Perrings, 2007). From an economic perspective, agrobiodiversity loss becomes a problem wherever it is socially inefficient (given social distributional priorities).

Many of the services provided by on-farm agrobiodiversity are not traded in markets, leading them to have no price in markets or, at the very best, to be undervalued. Furthermore, since, agrobiodiversity not only provides private on-farm benefits, but also quasi-public benefits such as improved pollination or control of pests or diseases that reduce production risks on neighboring farms, a market failure problem arises. Economic theory predicts that the inability by farmers to capture the value of such benefits leads to the underprovision of such services, in other words to a socially sub-optimal level of agrobiodiversity conservation at national, regional, and global levels (Drucker and Smale, 2007; Baumgartner, 2007; Pascual and Perrings, 2007). Policy interventions are therefore necessary to support the sustainable use and management of agrobiodiversity in order to fulfill the needs of society at large.

The field of agrobiodiversity economics recognizes that besides supply-side factors that may hamper access to resources required to maintain socially desired agrobiodiversity levels (e.g., access to seeds by farmers), the bulk of the problem behind agrobiodiversity loss is demand-based. Farmers’ individual decisions regarding the desired level of planned agrobiodiversity in their farms usually depend on conditions in the relevant agricultural markets (Smale *et al.*, 2001), and these often do not recognize the full suite of values of agrobiodiversity.

Although agrobiodiversity management decisions are taken at the farm-level, with the opportunity costs of conservation privately born by individual farmers, a significant part of the benefits from agrobiodiversity conservation accrue at the landscape (community), regional, and even global levels (O’Farrell and Anderson, 2010). Since the social benefits of higher levels of crop genetic diversity being conserved are not transmitted to those farmers who invest in their conservation, the latter have little or no private incentive to conserve agrobiodiversity (Perrings, 2001). The most profitable decision is to grow only a few crop varieties frequently, and not to invest in conservation of the varieties that are less “favored” by the market. In this sense, farmers who conserve and utilize on-farm or *in situ* crop genetic diversity are essentially conserving an impure public good that has significant global public spillover benefits and thus they can be seen as net-subsidizers

of modern agriculture and food consumers worldwide (Pascual and Perrings, 2007).

The case of underutilized crop species is an example of such market failure in agrobiodiversity. Following Gruère *et al.* (2009: p. 62), the notion of “underutilized” species can be applied to those landraces that simultaneously share the following three characteristics (1) they are locally abundant but globally rare, (2) local users have practical knowledge of them but scientific information about the species is scant, and (3) current use of the plant is limited relative to its economic potential. Minor millets (finger millet, kodo, barnyard, and little millet) in India are one example of underutilized species. Many other underutilized plant species are collected rather than cultivated (Padulosi *et al.*, 2002). The market failure associated with underutilized species stem from the fact that their real and potential economic value that surpasses their current (observed) value and this induces the socially sub-optimal provision of these species.

Besides the market failure associated with agrobiodiversity, there are important intervention or policy failures at the local, regional, and global scales that further distort farmers’ decision toward agrobiodiversity conservation. For instance, the bulk of subsidized inputs associated with intensive agriculture, free extension services, or market price support related to high yielding or improved plant genetic resources are sources of such policy failure (Drucker and Rodriguez, 2009). Additionally, as Pascual and Perrings (2007) note, other important institutional failures arise from the decisions of powerful intergovernmental organizations (World Bank, International Monetary Fund, and United Nations Development Programme) and international agreements (the General Agreement on Tariffs and Trade, the Sanitary and Phytosanitary Agreement, and the International Plant protection Convention). In some cases, they affect agrobiodiversity by limiting the choice of management strategy or technology used by farmers. In others, they work by encouraging the diffusion of new technologies or by dispersing new crop varieties, biocontrol agents, pests, and pathogens. As in the case of direct subsidies, these indirect influences on farmers’ decisions change the private returns on farm investments, often in ways that discourage agrobiodiversity conservation. Hence, from an economic viewpoint, the problem of agrobiodiversity loss can be interpreted as a typical market failure. It stems from the mixed public-good nature of agrobiodiversity conservation and the policy or institutional failures that make a biodiversity-based agriculture uncompetitive (e.g., through agricultural production subsidies, tax breaks, price controls, or incomplete property rights) and lack of appropriate governance structures that support its conservation (Pascual and Perrings, 2007).

Figure 2 describes a heuristic model adapted from Drucker and Rodriguez (2009) and Narloch *et al.* (2011a), and serves to illustrate the market failure problem associated with the socially suboptimal level of agrobiodiversity conservation and the displacement of local landraces or underutilized species by commercially improved, high yielding varieties from modern breeding programs (e.g., Brush and Perales, 2007).

Given local agroecosystem characteristics and local economic context, including prices of different crop varieties in the market or the implicit value attached to them by farmers, a

Figure 2 Replacement of a landrace by improved crop variety. Adapted from Drucker AG and Rodriguez LC (2009) Development, intensification and the conservation and sustainable use of farm animal genetic resources. In: Kontoleon A, Pasqual U, and Smale M (eds.) *Agrobiodiversity Conservation and Economic Development*, ch. 7, pp. 92–110. Abingdon, UK: Routledge, with permission from T&F.

local crop variety (or landrace) might be expected to outperform a higher yielding or improved variety at low levels of input intensification of the agricultural system, denoted by I^* . Here the term intensity is used in a general sense and includes also, *inter alia*, factors related to access to markets and extension services. The curves represent the profitability functions observed by farmers under full information. After $I^*(0)$ is reached, farmers face increasing incentives to replace the locally adapted landrace with the improved crop variety. The magnitude of such incentives is determined by the vertical distance between the two curves and represents the opportunity cost associated with the conservation and utilization of the local landrace.

As Drucker and Rodriguez (2009) argue, there are a number of reasons to suggest that the current replacement point, $I^*(0)$, is located to the left of the socially optimal replacement point, or $I^*(S)$, implying a suboptimal conservation of agrobiodiversity on-farm. The difference between $I^*(0)$ and $I^*(S)$ reflects a market failure. The distance increases in two cases. The first is where the perceived financial performance of the improved crop variety is artificially supported, for instance based on policies that support the free availability of improved seeds, capital subsidies for inputs such as fertilizer or pesticides, free or subsidized support services, or subsidized market prices associated with the improved variety instead of with the landrace. The second is where the possible public benefits of conservation, such as those associated with the provision of multiple ecosystem services and the potential nonuse values associated with local agrobiodiversity, including maintaining socio-cultural traditions, local identities, and traditional knowledge values, are ignored.

Figure 2 assumes that to the left of $I^*(0)$, farmers have financial incentives not to replace local crop varieties, and thus to conserve agrobiodiversity since this is what provides a higher economic return. Beyond $I^*(S)$, displacement of landraces by improved varieties would be economically justified. The dilemma occurs between these two points, that is, when

the displacement takes place between $I^*(0)$ and $I^*(S)$ as it is associated with a suboptimal loss of agrobiodiversity from a social perspective, while this might be privately optimal from the farmer's point of view. In this case, the additional loss of public and nonmarket values due to the erosion of agrobiodiversity outweighs the benefits of introducing the higher yielding variety.

As Drucker and Rodriguez (2009) and Narloch *et al.* (2011a) contend, from this heuristic model the solution to the social dilemma seems straightforward. Society should first demonstrate the public values of agrobiodiversity and design economic instruments so that farmers can capture the true economic value of on-farm agrobiodiversity. All distorting policies that bias against landraces artificially ought to be dismantled. These include, for example, subsidies to improved varieties that shift the curve for improved varieties downward and to the right (dotted line). In addition, by putting in place mechanisms to permit the “capture” of the total economic values associated with the use of landraces, the profitability curve for local varieties would shift upward to the left (dotted line). The next section addresses the value of agrobiodiversity and how this can be demonstrated. Policy mechanisms to capture and share the values are presented in the subsequent section.

The Value of Agrobiodiversity

Valuing biodiversity has been the focus of much research and debate in economics (e.g., Pearce and Moran, 1994; Nunes and van den Bergh, 2001; Pascual *et al.*, 2010). There is a growing theoretical and empirical literature, largely based on case studies, which forms one of the most fertile grounds of environmental economics. The economic value of biodiversity is an anthropocentric dimension of value and as such it can be used to complement, but not to substitute for, other legitimate ethical or scientific reasoning and arguments relating to biodiversity conservation (Turner and Daily, 2008). In essence, the economic value of biodiversity is one way to capture the intensity of people's preferences for changes in the quantity or quality of biodiversity. There is a growing realization among conservation biologists that demonstrating the value of biodiversity influences policy makers to increase conservation (Pascual *et al.*, 2010; ten Brink, 2011).

During the past decade, a small but growing literature on valuing crop and livestock agrobiodiversity emerged (e.g., Smale, 2006). The ongoing efforts to demonstrate the economic value of agrobiodiversity is generally seen as a first step in justifying its conservation through the design and implementation of policy instruments that can capture and share the benefits of conservation (Jackson *et al.*, 2007b; Pascual and Perrings, 2007). Demonstration refers to the identification and measurement of agrobiodiversity. Capture refers to the appropriation of biodiversity values through incentives for its conservation by those who ultimately bear the costs of conservation.

Agrobiodiversity is largely not priced by the market. Its value reflects a socially evolving context, and there are differences in the way that social groups calculate its worth (Pascual and Perrings, 2007; Pascual *et al.*, 2010). Price information on

agricultural genetic resources is sparse, mainly because the attributes or traits of such resources are not easily identifiable even by those managing them, such as farmers. Compared to wild biodiversity, proportionately more of the economic value of (domesticated) agrobiodiversity is related to use rather than nonuse values, although the latter can be important in certain contexts associated with farmers' cultural identity and the maintenance of traditional knowledge (Cicia *et al.*, 2003; Smale, 2006; Smale and Drucker, 2009).

As pointed out by the Millennium Ecosystem Assessment (MEA) "...where agriculture already dominates landscapes, the maintenance of biodiversity within these areas is an important component of total biodiversity conservation efforts, and, if managed appropriately, can also contribute to agricultural productivity and sustainability through the ecosystem services that biodiversity provides (such as through pest control, pollination, soil fertility, protection of water courses against soil erosion, and the removal of excessive nutrients)" (MEA, 2005: p. 13). These regulating and supporting ecosystem services, largely associated with resilience at the landscape level, are quite distinct from those typically associated with forest ecosystems and the carbon sequestration services they provide. An additional distinction is that, unlike most wild biodiversity, agrobiodiversity has mixed-good properties. As discussed by Smale (2006), it has an impure public good characteristic as it shares properties of a private good (rival in use and excludability possibility) as well as public good (low rivalry and low excludability). While seed is clearly rival and the cost of exclusion is low, the genetic information embodied in the seed is non rival and the cost of controlling its use can be costly. Similarly, seeds as planting material can be considered a private good consumed as a production input, with no two farmers planting the same unit of seed, but the genetic resources embodied in the diversity of seeds is a public good for those two farmers. This public good aspect also extends to the functionality of the underlying seed system that allows evolutionary processes to be maintained, as well as the underlying traditional knowledge related to the management of use of the genetic resource in question. Furthermore, biodiversity has an option value for future generations in terms of beneficial traits for breeding new varieties adapted to changing environmental conditions.

Private versus Public Value of Agrobiodiversity

Underutilized or neglected species of minor or major crops provide important plant genetic diversity worldwide and they are associated with all three types of values. Gruère *et al.* (2009) provide a conceptual framework to guide empirical analysis of changes in use of underutilized species and policy options to conserve them. The value of underutilized plant species involves two components: a private and public value component. The public component includes the value of improved nutrition to both current and future generations, the mitigation of private production risks, and the nonuse values associated with tradition and culture (Gruère *et al.*, 2009). They propose a classification of underutilized plant species based on their private and public value. By definition, the observed value of any underutilized plant species is inferior to its potential value (Figure 3).

Figure 3 Characterization of underutilized plant species according to private and public values. Reproduced from Gruère G, Giuliani A, and Smale M (2009) Marketing underutilized plant species for the poor: A conceptual framework. In: Kontoleon A, Pascual U, and Smale M (eds.) *Agrobiodiversity Conservation and Economic Development*, ch. 5, pp. 62–81. Abingdon, UK: Routledge, with permission from T&F.

A given underutilized plant species is represented by an outward vector linking its observed value to its potential (current or expressed) value, with the origin of the vector being the observed value. The current or observed value of the species can be located in Region 1, 2, or 3 but not in region 4 as by definition species that have both high private and public values cannot be identified as being underutilized (Padulosi *et al.*, 2002). Gruère *et al.* (2009) identify five types of directional vectors, each representing a different type of underutilized species. The horizontal vectors A and B represent species that are neglected by policy-makers despite their known contribution as public goods. Vectors C and D both have a vertical direction representing species for which their current or observed private value is inferior to their private potential value. In this case, public intervention could be geared to help markets function better. Finally Vector E is associated with a species that currently has a lower private and public value than what could be potentially realized. This categorization allows us to identify alternative types of intervention related to the need for enhancement of private good and/or the capture of public good values to support the maintenance of agrobiodiversity.

While many underutilized plant species are locally valued as revealed by their use based on traditional knowledge, the potential public value often arises through new scientific evidence related to their intrinsic properties, or due to changing consumer preferences in turn linked to evolving cultural trends or fashion. For example quinoa (*Chenopodium quinoa*), typically grown in the Andean altiplano of Bolivia and Peru, has become fashionable in urban areas of developing and developed countries (Gruère *et al.*, 2009).

The Total Economic Value of Agrobiodiversity

The value of agrobiodiversity is generally argued to comprise: (1) the private benefits to farmers via the consumption and production values they derive from producing crops; (2) private, as well as locally and regionally public benefits to farmers, and to consumers, when the choices make farming more resilient to biotic and abiotic stresses; and (3) global

public benefits to future farmers, plant breeders, and consumers, when the choices they make protect against genetic erosion (Lipper and Cooper, 2009, p. 30). These types of value are associated with a direct (private) use value, a local public indirect use value, and global public option/bequest values, respectively. These are described in the next section.

Direct Use Value

Current direct use values are most obvious when referring to plant genetic resources and refer to the harvest and use of crop varieties in noncommercial or commercial/industrial processes. They derive from the utility gained by an individual from the consumption of a good or service or from the consumption by others of a good or service associated with agrobiodiversity (Smale, 2006). They reflect the production and consumption benefits of agrobiodiversity. For example, the financial rate of return to investment in plant breeding programs in the development of world agriculture has been demonstrated to be significant, and to generate economic returns that far outweigh the costs of investment (Alston *et al.*, 2000; Evenson and Gollin, 2003). The use of genetic resources for plant breeding that lowers food prices in less developed countries is especially relevant, as these consumers generally spend a greater share of their income on food than consumers in more developed countries (Drucker and Smale, 2007). Studies to date attest to the significant net marginal benefits of exploiting individual genetic accessions in commercial agricultural use versus conserving it in *ex situ* facilities such as large national and international gene banks (Gollin *et al.*, 2000, Koo *et al.*, 2004, Drucker and Smale, 2007).

For on-farm agrobiodiversity, Bellon (2009) argues that most studies of the benefits associated with maintaining crop diversity on-farm link them to the provision of local private goods and services to farmers (see e.g., Smale, 2006), to the provision of desirable varieties to other farmers in a particular community or region (e.g., Badstue *et al.*, 2006; Stromberg *et al.*, 2010), and to the management of tolerance to stress, pests and diseases (a quasipublic good) (e.g., Jarvis *et al.*, 2011).

The economic valuation of agrobiodiversity includes both studies of farmers' revealed preferences and surveys to elicit preference over a range of crops, farmers' socio-economic and agroecological environments. Case studies support the notion that farmers value various dimensions of agrobiodiversity. From these studies, the data indicate that often farmers in less productive and more remote regions value agrobiodiversity the most (Smale, 2006).

Understanding farmers' choices regarding crop diversity (Van Dusen and Taylor, 2005; Birol *et al.*, 2006, 2008) and varietal traits affecting productivity, environmental adaptability, and yield stability (Gemessa and Zander, 2010; Pant *et al.*, 2010) is key to developing incentives for agrobiodiversity conservation. Stated preference methods to estimate farmers' willingness to pay for different agrobiodiversity attributes show that farmers' preferences for variety attributes are shaped by economic (resource constraints, markets, and risk) as well as by noneconomic factors, including cultural norms and attitudes. In addition, farmers' demand for varieties also depends on consumers' preferences for valuable attributes embodied in landraces such as taste, aroma, etc. Through

attribute preference analysis based on hedonic pricing models, consumers' willingness to pay for different traits of landraces have been estimated for crops such as eggplants in India (Krishna *et al.*, 2010) and rice in Nepal (Pant *et al.*, 2010).

Other studies have focused mainly on the productivity effects of agrobiodiversity to derive their economic value. When on-farm biodiversity supports the productivity of crops by enhancing yields or their stability, or by substituting for the use of purchased inputs such as pesticides, agrobiodiversity has an instrumental or "use-value" for farmers. In addition, a direct consumptive value refers to the benefits that consumers, including farmers, obtain from being able to access a greater variety of foods to support food security through a more diverse diet, taste preferences, cooking characteristics, and storage (FAO, 2009). Based on the MEA framework, direct use values are associated with provisioning services of agrobiodiversity. More specifically, production benefits refer to supporting mean productivity as well as stability of yields especially in areas prone to significant environmental (e.g., pest, disease, and competition), climatic and/or economic risks.

Besides theoretical models linking agrobiodiversity and productivity (e.g., Omer *et al.*, 2010), other economic approaches linking genetic diversity to crop productivity have econometrically estimated mean-variance production functions to test the relationship of crop biodiversity to mean yield productivity and variability. As Drucker and Smale (2007) point out findings are rather location-, time-period-, and cropping-system-specific. In their groundbreaking studies Smale *et al.* (1998) on wheat production in the Punjab of Pakistan and Widawsky and Rozzelle (1998) on rice production in China used the Just and Pope-type stochastic production function approach. While Smale *et al.* (1998) found that in rainfed districts, crop genetic diversity was linked positively to mean yield levels and negatively to yield variance, Widawsky and Rozzelle (1998) found that diversity was instead negatively related to both mean and variance of yields. In an extended approach to account for risk aversion to crop failure (downside risk exposure) in rainfed durum wheat farming in Sicily (Italy), Di Falco and Chavas (2006) have shown that under low pesticide use, crop genetic diversity can increase farm productivity and reduce yield variance. Additionally, when longer-term effects can be factored in, spatial genetic diversity appears to be linked with greater productivity in more intensive cereal-based agroecosystems (Omer *et al.*, 2007; Di Falco and Chavas, 2008).

Indirect Use Value

The indirect use value of agrobiodiversity refers to the environmental services rendered by agrobiodiversity in providing stability of yields, thus reducing the risk of crop failure. It has been noted that risk-averse farmers use crop diversity in order to hedge their income risk (Birol *et al.*, 2006, Di Falco and Perrings, 2003; Di Falco and Chavas, 2009). This is akin to considering investment in agrobiodiversity as a form of "self insurance" by risk-averse farmers who act *ex ante* in order to reduce a potential income loss, such as reliance on landraces by the most vulnerable farmers in a drought-prone region (Cavatassi *et al.*, 2011). In addition to the private decisions by individual risk-averse farmers faced with risk of crop failure, the natural insurance mechanism of

agrobiodiversity is also associated with a broader notion of social-ecological resilience delivering important public benefits at the local and regional level (Pascual and Perrings, 2007). The public insurance value of agrobiodiversity stems from the notion that a more biodiverse agricultural system allows the system to absorb higher disturbance levels, be it climatic, environmental, or economic, and still remain within the same state while being able to self-organize and have the capacity for learning and adaptation (Carpenter *et al.*, 2001).

In this vein, the public value of agrobiodiversity is also associated with the capacity of the agricultural system to adapt to economic or environmental external changes. For instance, multicrop and tree biodiversity in agroecosystems can enhance the ability of farmers to remain economically viable by diversifying revenues affected by volatile international market prices for inputs, crops, or tree products (Lin, 2011). In other words, in intensive agricultural systems with low levels of agrobiodiversity, and high dependence on the use of non-renewable inputs, the cost of eroding agrobiodiversity is that the system gets locked into a narrow range of highly productive and stable (under low perturbations) agricultural technologies. But this reduces the capacity of the system to absorb greater environmental or economic shocks, such as sudden and unexpected commodity price changes or climatic extreme events, especially where other supporting mechanisms (government subsidies and extension services) may not be sufficient. By eliminating options toward productive diversification, a reduction in agrobiodiversity may also lock farmers into obsolete agricultural technologies (Perrings, 1998).

While there are some economic studies that explore the private insurance value of agrobiodiversity (Cavatassi *et al.*, 2011), the public insurance value of crop diversity in regulating ecosystem services at the landscape level (e.g., pollination, water retention) is not yet fully supported empirically. However, a view is emerging that links the broader notion of agrobiodiversity at the landscape level (beyond crop diversity) with the regulating ecosystem services, and so identifies positive spill-over effects of agrobiodiversity on local on-farm productivity and stability, especially under global perturbations (Chapin *et al.*, 2000; Folke *et al.*, 2004; Tschamntke *et al.*, 2005; Jackson *et al.*, 2007a,b). Often this is associated with species in neighboring ecosystems that provide pollination and biological control services against pests and invasive species that, in turn, can imply significant cost savings to farmers (Ricketts *et al.*, 2004; Perrings, 2005; Tschamntke *et al.*, 2012). In addition, genetic diversity may contribute to an array of ecosystem services by facilitating evolutionary processes *in situ* that select for better-adapted crop varieties (Faith *et al.*, 2010).

The private indirect use value for farmers is based on the private (natural) insurance value that agrobiodiversity offers. Reliance on agrobiodiversity to manage risk can be affected by agricultural policies such as subsidized crop yield insurance or direct financial assistance (Di Falco and Perrings, 2005) as well as the existence of financial insurance institutions. Market insurance products can serve as a substitute for self-insurance through agrobiodiversity investments by risk-averse farmers. The insurance issue is addressed in a model developed by Quaas and Baumgärtner (2008) and Baumgärtner and Quaas

(2009). In this model it is shown that the price of financial insurance has an impact on the level of on-farm agrobiodiversity managed for risk management purposes. The model also shows that as financial insurance becomes cheaper, it can optimally drive out agrobiodiversity. In addition, in the case of agrobiodiversity having a quasipublic good characteristic, i.e., when it has positive spill-over effects in turn leading to market failure, the trade-off between improved access to financial insurance and lower agrobiodiversity conservation has ambiguous welfare effects and these mainly depend on agroecosystem properties (Quaas and Baumgärtner, 2008). They show that when the private insurance value of agrobiodiversity is low compared to its public insurance value, then improved access to financial insurance can have a negative impact on total welfare at the local or regional scale. The public insurance value stems from the local and regional stability and wider societal benefits that are not directly associated with harvest or consumption at the plot or farm level.

Agrobiodiversity through its insurance mechanism may not generally be enough to justify conservation by an individual farmer when there is easy access to improved artificial capital inputs, for example, fertilizers, improved seeds, etc. However where financial insurance markets are thin or non-existent, or access to intensive agricultural technologies is restricted, there is some evidence that agrobiodiversity can mitigate production and consumption vulnerability in marginal environments. This evidence is still sparse, even if it is well known that farmers manage risk through crop or varietal choices in their *ex ante* farm production decisions (Smale *et al.*, 1998; Di Falco and Chavas, 2006). For example, Di Falco and Chavas (2008, 2009) have showed that in areas prone to production failure due to lack of rainfall, such as in the South of Italy and in the Tigray region of Ethiopia, respectively, crop agrobiodiversity is used to buffer negative productivity effects of declining rainfall levels.

Global Option Value

The option value of agrobiodiversity is the value of the option to use it under future uncertain technological, market, or environmental conditions (Smale, 2006). (While agrobiodiversity may also have existence and bequest values, these are likely to be relatively unimportant both compared to the other types of value generated by agrobiodiversity, as well as to that of wild biodiversity in general. We therefore do not further consider such nonuse values in this article.) This type of value is not necessarily factored in by individual farmers in their decentralized decisions and instead may be associated with the maintenance of crop evolutionary processes (Brush, 2000, chapter 1). As Bellon (2009) argues, by conserving landraces we keep the option for the generation of new and improved crop varieties. Agrobiodiversity is the basis for scientific plant breeding and farmers to adapt crops to heterogeneous and changing environments in order to increase agricultural productivity as well as stability of production by providing, for example, environmental stress and resistance to pests and diseases. There is ample evidence that continuing releases of improved varieties, based on conserved genetic resources, have generated economic returns that far outweigh the costs of investment (Qualset and Shands, 2005). Further, the global option value of agrobiodiversity is considered to be very

significant especially in the face of climate change as it can provide natural insurance for an unpredictable future (Ceccarelli *et al.*, 2010; FAO, 2010; Pascual *et al.*, 2011). But while some case studies exist at the local level that link farmers' *ex ante* agrobiodiversity choices to climatic risk exposure (e.g., Di Falco and Chavas, 2009; Cavatassi *et al.*, 2011), the global option value of both *ex situ* and *in situ* agrobiodiversity in terms of uncertainty to global economic and climatic changes represents a significant research gap.

Economic Instruments for Agrobiodiversity Conservation

A significant policy challenge is that most of the globally valuable agro-biodiverse landscapes are located in poor and often marginal regions of the world exposed to rapid social and economic change (Drucker and Smale, 2007). Further, market developments have major impacts on agrobiodiversity by affecting farmers' choice of crops and varieties (Lipper *et al.*, 2009) and by reducing the probability that farmers will cultivate traditional varieties that add to both intra (or varietal)- and intercrop diversity (van Dusen and Taylor, 2005; Smale, 2006). Hence in the context of rapid economic change in developing countries, incentive mechanisms for *in situ* agrobiodiversity conservation are being devised. Noneconomic policy instruments attempt to influence farmers' decisions toward conservation through moral suasion, regulation, and planning (Pascual and Perrings, 2007). The supply of, and demand for, genetic resources by farmers depends both on relative prices and on regulations governing plant breeding and the seed sector (Lipper and Cooper, 2009). While most regulations related to land use in agricultural landscapes affect agrobiodiversity indirectly, various national and international regulatory frameworks exist to support agrobiodiversity, such as the International Treaty on Plant Genetic Resources for Food and Agriculture (ITPGRFA).

The ITPGRFA entered into force in 2004 as a legally binding international agreement that promotes the conservation and sustainable use of PGRFA and the fair and equitable sharing of the benefits arising out of their use, in line with the Convention on Biological Diversity (FAO, 2009). The ITPGRFA has established a multilateral system of access and benefit sharing to facilitate access to plant genetic resources of the most important crops for food security. It involves 126 countries plus the European Union. The Convention on Biological Diversity (CBD), which views *in situ* conservation as the preferred approach, has called for the development of positive incentives (COP 10 Decision X/2) for conservation as part of its Strategic Plan for 2011–2020 (see <http://www.cbd.int/decision/cop/?id=12268>). In addition, a handful of countries worldwide are experimenting with new ways of protecting and rewarding traditional knowledge through the realization of Farmers' Rights by national governments, as explicitly called for Article 9 of the ITPGRFA (FAO, 2009). It is therefore apparent that innovative policy instruments are being seen as necessary to facilitate and enhance incentives for farmers to utilize and conserve agrobiodiversity.

As is the case for biodiversity in general, a partial solution may lie within the market system itself without explicit need

for government intervention, i.e., market formation for agrobiodiversity conservation (Pascual and Perrings, 2007; Perrings *et al.*, 2009). The idea is that since conserving on-farm agrobiodiversity can yield goods and services valued beyond the farm, in certain circumstances, these could be traded in the market and doing so could generate income for farmers, making on-farm conservation financially viable for them. The challenge is thus to identify the specific components of agrobiodiversity that can be shown to provide benefits for different consumers at different scales. There are two main types of market instruments for agrobiodiversity: (1) those that stimulate market value chains for landrace-derived commodities, including through the use of labeling and certification schemes, and (2) voluntary direct payments to farmers. Both can be seen as complementary. While emergent economic theories and applications are being developed about such instruments, to date they remain to be mainstreamed into policy making.

Market Value Chain Development

Developing market value chains for crop genetic resources (CGR) offers an opportunity to link farmers' incomes and the diversity of crops and varieties that they manage. The idea is that adding value to the products derived from traditional varieties means that consumer demand for the crop can increase its market price and the income received by farmers. Promoting such value chains for agrobiodiversity is thus seen as one sustainable way to maintain the cultivation of targeted landraces and to inform which types of landraces could succeed along the value chain (Will, 2008; Gruère *et al.*, 2009; Wale *et al.*, 2010).

A value chain approach regarding plant genetic resources targeted for conservation can be promoted through eco-labeling, certification, or origin schemes, which highlight the specific attributes of agro-biodiversity related commodities (Hermann and Bernet, 2009). While there is ample experience with eco-labels in developed countries (Basu *et al.*, 2003) to support products derived from traditional plant genetic resources, the potential marketability of traditional crop varieties through labeling and certification in developing countries is also gaining attention (Kruijssen *et al.*, 2009; Gautam and Paant, 2010). For example, Hellin *et al.* (2010) points to a number of successful experiences in developing countries, such as with native potatoes and quinoa in the Andes, maize landraces in Mexico, capers in Syria, and minor millets in India. However, there are few studies that estimate both the implicit consumer willingness to pay for landraces and farmer willingness to accept compensation, especially in contexts where higher yielding varieties exist. An exception is Krishna *et al.* (2010), who have demonstrated, for the case of eggplant landraces in India, that the implicit price premium urban consumers are willing to pay for landraces instead of modern (hybrid) eggplant varieties can compensate for the lower productivity of the former.

However, although it has been shown that market value chain development can facilitate the conservation through sustainable use of "neglected and underutilized" or traditional crop species/varieties by enhancing the values of such CGR

(amongst others see: Hoeschle-Zeledon *et al.*, 2009; Padulosi *et al.*, 2009; Rojas *et al.*, 2009, respectively, for Italian hulled wheat, Indian minor millets, and Andean grain examples), the potential to use such an approach as part of a strategic national agrobiodiversity conservation program remains to be established. Indeed, Narloch *et al.* (2011a) noted that “relying solely on market development might be a dangerous strategy for the conservation of a diverse genetic resource pool, especially as market conditions can change rapidly and generally consumers and agribusiness tend to favor a narrow suite of crop species/varieties.”

In fact, in order for such market value chain development interventions to be able to effectively contribute to such a strategic national program, a number of challenges need to be considered. These include:

1. The market potential of priority crop genetic resources for conservation: Not every crop species/variety within a priority conservation portfolio (i.e., the strategically selected set of crop species/varieties considered to be priorities for conservation given their contribution to overall diversity and their current threat levels and conservation costs) will necessarily have improved marketing potential. In fact, in the absence of a strategic approach, market value chain development interventions would instead tend to focus on high market potential traditional crop species that may either be unthreatened or only locally threatened.
2. Initial investment costs and long-term success rates: Not every niche product development project is successful and initial investment requirements may be high. Generating appropriate product volumes for market may also be far greater than those required to achieve modest conservation goals.
3. Displacement/leakage: Market development may be so successful that it displaces other priority crop species/varieties. Examples of such displacement include minor millets in India (Padulosi *et al.*, 2009), Andean grains in Latin America (Rojas *et al.*, 2009), potatoes in the Andes, and capers in Syria (Hellin *et al.*, 2010). In such cases, farmer-selection to conform to characteristics demanded by the market has reduced the suite of other characteristics associated with local varieties.

Given this, it is worth exploring the potential for recently developed payment for agrobiodiversity conservation services (PACS) incentive schemes to overcome some of these challenges. Such schemes, which are discussed further below, have been shown to be a potentially effective instrument for promoting the cost-effective maintenance of threatened crop varieties while accounting for social equity considerations.

Voluntary Direct Payments

The creation of markets for biodiversity can also involve direct payments (Ferraro, 2001; Ferraro and Simpson, 2002). These include payment for ecosystem services (PES), which build on compensation flows from the beneficiaries of an ecosystem service to the providers of that service (Engel *et al.*, 2008; Muradian *et al.*, 2010). PES has been hailed as a promising solution for conservation dilemmas in many different

contexts, but mainly in the contexts of forest conservation in developing countries (Wunder *et al.*, 2008) following the so-called ‘Provider Gets Principle’ (Hodge, 2000).

In developed countries, such as in EU, there are payments to farmers to change agricultural practices toward more biodiversity- and ecosystem-friendly practices (Kleijn and Sutherland, 2003). These resemble PES, though the buyer in this case is not a direct beneficiary but a government institution. There are few examples of such types of PES in agricultural landscapes in developing countries. These include paying farmers in silvopastoral systems to manage diverse ecosystems services, to introduce natural vegetation contour strips in farmers’ plots, and to integrate short-term improved fallow systems and shade-grown coffee cultivation (FAO, 2007b; Lipper *et al.*, 2009).

To date, however, only a couple of PES-like schemes have been applied to conserve plant genetic diversity worldwide. While not presented as a PES scheme, a Global Environmental Facility project in Ethiopia involved paying farmers for conserving traditional sorghum varieties based on an incremental cost approach related to the yield gap between traditional and improved varieties (Wale, 2008). Recently a novel approach, known as PPACS, which is a subcategory of agriculture-related PES, has focused specifically on socially valuable and threatened local plant genetic resources (Narloch *et al.*, 2011a, b). Such schemes may be viewed as an economic instrument to tackle the market, policy, and global appropriation failures associated with the public good characteristics of agrobiodiversity conservation services through the use of (monetary or in-kind) reward mechanisms in order to increase the private benefits of agrobiodiversity conservation to farmers.

Given that the marginal commercial value of large scale on-farm agrobiodiversity conservation for the private sector may not be an option, it may be expected that government agencies and NGOs at a local, regional, national, or even international level may be required to take the role of the beneficiary payer in PACS (Narloch *et al.*, 2011a). Furthermore, the implementation of a PACS approach requires a prioritization of the targeted threatened genetic resources, as well as the definition of conservation goals (trade-offs may exist between environmental effectiveness, economic efficiency, and social equity – see Narloch *et al.*, 2011b) and the levels of conservation required to achieve the provision of given ecosystem services derived from agrobiodiversity. Such levels may be associated with safe minimum populations, in turn related to land areas, farmer/community numbers and their spatial distribution, the functionality of local seed systems, and the maintenance of traditional knowledge and culture.

To date, only one such PACS scheme for plant genetic resources has been designed and implemented in the context of on-farm agrobiodiversity conservation. This PACS scheme was implemented in the Bolivian and Peruvian Andean altiplano based on a reverse tender approach at the community level. It includes in-kind payments with the objective of conserving endangered quinoa landraces (Narloch *et al.*, 2011b (Figure 4).

However, PACS or other incentive schemes based around direct payments also have their limitations, particularly with regard to issues related to the sustainability of their funding. It may therefore be that the two types of market creation

Figure 4 Andean farmers conserving quinoa landraces through a competitive tender PACS approach.

instruments (i.e., market chain and PACS approaches) should be seen as complements rather than as substitutes.

In terms of addressing the market development challenges (1–3) highlighted above, it might be expected that a complementary PACS scheme could ensure that market development efforts are focused on priority threatened species/varieties, and the protection of safe minimum populations (Drucker, 2006) of specific threatened crop genetic resources. Furthermore, a PACS approach could facilitate adequate evaluation through farmer experimentation of specific crop genetic resources that are no longer widely used. The overall goal, of course, is that through time-limited PACS support, threatened crop genetic resources would have a potential market. Others would continue to depend on alternative sources of sustainable financing or *ex situ* conservation.

Under such a complementary approach, market value chain development could be used to support the financial sustainability of PACS, while PACS could support the environmental sustainability of the market chain. However, the framework for undertaking a comparative analysis and exploring potential complementarities remains to be developed and a number of key economic and underlying questions need to be answered. These include:

1. the degree to which crop genetic resources within a typical priority conservation portfolio have market potential;
2. the initial investment costs and long-term success rates of agrobiodiversity-based market value chain development (and the volumes required for such market development);
3. how such volumes and costs compare to that required to ensure that an *in situ* population of the crop species/variety in question is considered to be not at risk, as well as how such a safe minimum population can be defined and how can it be linked with the actual provision of specific ecosystem services;
4. how a safe minimum population is spatially distributed (geographically but also in terms of farmer and community numbers) so as to reduce risk of catastrophic loss, as well as help maintain evolutionary processes, seed system functionality, and indigenous knowledge.

Glossary

Consumer surplus A measure of the welfare that people gain from the consumption of goods and services, usually measured as the difference between the price that they are actually willing and able to pay for a good or service and the actual market price.

Direct use values Benefits gained through consumptive and nonconsumptive uses that involve some form of direct physical interaction with environmental goods and services, such as recreational activities, resource harvesting, drinking clean water, breathing unpolluted air, and so forth.

Economic valuation The various methods used by economists to determine the willingness to pay of individuals for the benefits derived from ecosystems, many of which are nonmarketed.

Ecosystem functions Biogeochemical cycling, including primary production (photosynthesis), nutrient and water cycling, and materials decomposition, and the flow, storage and transformation of materials, and energy through an ecosystem, including through food web processes such as pollination, predation, and parasitism.

Ecosystem services The benefits (i.e., goods and services) people obtain from ecosystems.

Ecosystem structure The biotic (living) and abiotic (nonliving) components of an ecosystem, and the interactions between them.

Indirect use values Ecosystem services or benefits whose values can only be measured indirectly, since they are derived from supporting and protecting activities that have directly measurable values (e.g., coastal habitat as breeding and nursery grounds for off-shore fisheries; coral reefs providing protection against storm surge; upper watershed forests controlling soil erosion and runoff).

Nonuse values Values ascribed to the natural environment that are independent of any human interaction with it; for example, an individual valuing the pure "existence" of a natural habitat or ecosystem or wanting to "bequest" it to future generations.

Producer surplus A measure of the welfare that producers gain from selling goods and services, usually measured as the difference between the actual market price and the minimum amount that they would be willing to accept for the good or service.

Regulating services The benefits obtained from the regulation of ecosystem processes, including flood protection, climate regulation, human disease regulation, water purification, air quality maintenance, pollination, and pest control.

Introduction

The Millennium Ecosystem Assessment defines ecosystem services as "the benefits people obtain from ecosystems" (MA 2005). Among the myriad types of benefits that arise through normal ecosystem functioning, a subset can be defined as *regulating services*. These are the benefits obtained from the regulation of ecosystem processes, and include flood protection, climate regulation, human disease regulation, water purification, air quality maintenance, pollination, and pest control.

As indicated in Table 1, many important regulating services are declining globally due to human-induced change to ecosystems. The main reason for this loss is because we have failed to value these benefits adequately. Too often, economic development decisions are taken that harm ecosystems and the services they provide, because the value of important ecosystem services is either ignored or unknown. Because they are the most difficult to value, important regulating services are usually the main ecosystem benefits that are not considered in decisions to convert or exploit natural habitats.

However, recent interest in regulating services has grown because of concerns of the global impacts of climate change, including effects on future freshwater supplies, the spread of disease and pests, degradation of forest and wetland habitats,

and biological invasions. The 2004 Indian Ocean Tsunami and the 2005 Hurricanes Katrina and Rita have also increased interest in the storm protection and food control benefits of coastal ecosystems.

Although the ecological analysis of key regulatory ecosystem functions has been well established, the economic valuation of the benefits provided by these functions is relatively new. As a report from The US National Research Council (2005, p. 2) has emphasized, "the fundamental challenge of valuing ecosystem services lies in providing an explicit description and adequate assessment of the links between the structure and functions of natural systems, the benefits (i.e., goods and services) derived by humanity, and their subsequent values". Moreover, it has been increasingly recognized by economists and ecologists that the greatest "challenge" they face is in valuing the ecosystem services provided by ecosystem regulatory functions.

The following reviews current efforts to develop the economic analysis of regulating services. As these services arise through the regulatory functioning of ecosystems, the review begins by briefly outlining this critical ecological production process (The linkages between biodiversity and ecosystem function are also addressed in two articles of this encyclopedia.) A further problem is that regulating services are not marketed. In addition, for many regulating services, there is

Table 1 Global status of key ecosystem services

<i>Condition globally has been enhanced</i>	<i>Condition globally has been degraded</i>	<i>Condition globally is mixed</i>
Crops	Capture fisheries	Timber
Livestock	Wild foods	Cotton, hemp, silk, and other fiber crops
Aquaculture	Wood fuel	Water regulation
Global climate regulation	Genetic resources	Disease regulation
	Biochemicals, natural medicines, and pharmaceuticals	Recreation and ecotourism
	Fresh water	
	Air quality regulation	
	Regional and local climate regulation	
	Erosion regulation	
	Water purification and waste treatment	
	Pest regulation	
	Pollination	
	Natural hazard regulation	
	Spiritual and religious values	
	Esthetic values	

Notes: Enhancement is defined as either increased production of or change in the ecosystem good or service that leads to greater benefits for people.

Degradation is defined as if current use exceeds sustainable levels, or a reduction in the benefits obtained from the good or service due to either some human-induced change or use exceeding its limits.

Mixed status implies that the condition of the good or the service globally has experienced enhancement in some regions but degradation in others.

inadequate knowledge to link changes in ecosystem structure and function to the production of these valuable benefits. These measurement issues are important limitations to the valuation of regulating services, and thus much of the review discusses how economists, ecologists, and other natural scientists are collaborating on overcoming such challenges. To illustrate the significance of valuing regulating services to development versus conservation decisions, a case study of mangrove conversion to shrimp farming in Thailand will be discussed in detail. Finally, there is growing awareness that the regulatory functions underlying key services are often influenced by the spatial extent, or scale, of ecosystems. As a consequence, the value of regulating services will vary across an ecological landscape. The significance of spatially varying regulating services for conservation versus development decisions is shown with the example of storm protection provided by mangroves in the Thailand case study.

Ecosystems, Biodiversity, and Regulating Services

Within its prescribed area or location, an ecosystem comprises its abiotic (nonliving) environment and the biotic (living) groupings of plant and animal species, or communities. The biotic and abiotic components, and the interactions between them, are often referred to as the *ecosystem structure*.

Two important *ecosystem functions* are carried out in every ecosystem: biogeochemical cycling and flow of energy. Important processes of biogeochemical cycling include primary production (photosynthesis), nutrient and water cycling, and materials decomposition. The flow, storage, and transformation of materials and energy through the system are also influenced by processes that link organisms with each other, such as the food web, which is made up of interlocking food chains. These food chains are often characterized by other important functions, such as pollination, predation, and parasitism.

Increasingly, evidence suggests that biodiversity plays a pivotal role in ecosystem functioning (Duffy, 2009; Duffy *et al.*, 2007; Naeem *et al.*, 2009). The consequence, as described by Levin and Lubchenco (2008, p. 30), is that diversity and heterogeneity is also critical to the adaptability of an ecosystem, and "lowered diversity exposes ecosystems to catastrophic change".

The structure and functions of an ecosystem provide valuable goods and services to humans. For example, some of the living organisms found in an ecosystem might be harvested or hunted for food, collected for raw materials, or simply valued because they are esthetically pleasing. Some of the ecosystem functions, such as nutrient and water cycling, can also benefit humans through purifying water, controlling floods, recharging aquifers, reducing pollution, or simply by providing more pleasing environments for recreation. These various benefits provided by an ecosystem via its structure and functions are now referred to as *ecosystem services* (Millennium Ecosystem Assessment, 2005).

However, it is important to recognize that the structure and functions of an ecosystem are not synonymous with its services or economic benefits. Ecosystem structure and functions describe the components of an ecosystem and its biophysical relationship regardless of whether or not humans benefit from them. Only if they contribute to human well-being do these components and relationships generate an "ecosystem service". The role of economic valuation is to determine how changes in ecosystem goods and services affect an individual's well-being, and then to determine how much the individual is either willing to pay for changes that have a positive welfare impact, or conversely, how much the individual is willing to accept as compensation to avoid a negative effect. In other words, the *ecological production* of ecosystem services is linked to the *economic valuation* of these services, but these two relationships are distinct (Barbier, 2007, 2011; Barbier *et al.*, 2009).

Figure 1 provides a visual summary of the links between the structure and function of ecosystems, the ecological

Figure 1 Links between the structure and function of ecosystems, the ecological production of ecosystem goods and services, and the economic valuation of the latter benefits.

Table 2 Some regulating services of ecosystems

<i>Ecosystem regulatory functions</i>	<i>Ecosystem processes and components</i>	<i>Ecosystem services (benefits)</i>
Gas regulation	Role of ecosystems in biogeochemical processes	Ultraviolet-B protection Maintenance of air quality Influence of climate
Climate regulation	Influence of land cover and biologically mediated processes	Maintenance of temperature, precipitation
Disturbance prevention	Influence of system structure on dampening environmental disturbance	Storm protection Flood mitigation
Water regulation	Role of land cover in regulating runoff, river discharge and infiltration	Drainage and natural irrigation Flood mitigation Groundwater recharge
Soil retention	Role of vegetation root matrix and soil biota in soil structure	Maintenance of arable land Prevention of damage from erosion and siltation
Soil formation	Weathering of rock and organic matter accumulation	Maintenance of productivity on arable land
Nutrient regulation	Role of biota in storage and recycling of nutrients	Maintenance of productive ecosystems
Waste treatment	Removal or breakdown of nutrients and compounds	Pollution control and detoxification

production of ecosystem goods and services, and the economic valuation of the latter benefits. Human drivers of ecosystem change affect important ecosystem processes and functions and their controlling components. Assessing this change is crucial yet difficult. However, even more challenging is determining how the ecological production of ecosystem goods and services arises from the structure and functions of an ecosystem. Probably the greatest remaining difficulty in the successful valuation of ecosystem goods and services is to integrate studies of the ecological production function (PF) with nonmarket valuation of the resulting benefits.

Thus, mapping ecosystem structure and function to a flow of ecosystem services that can then be valued is no easy task. This is especially the case for regulating services. As Table 2 indicates, for these services, we are beginning to understand how certain ecosystem regulatory functions, moderated by key ecosystem processes and components, yield a range of ecosystem services. Many of these benefits, such as storm and flood protection, climate regulation, and water purification, are highly valuable. As human economic activities exploit, degrade, and convert ecosystems, many such important regulating services will be affected. But tracing through the

resulting changes in ecosystem structure and function to the impacts on various regulating services, and finally, to the effects on human welfare requires overcoming a number of measurement challenges.

Measurement challenges

The most significant problem is that regulating services are not marketed. These services arise from ecosystem processes and functions that benefit human beings largely without any additional input from them. This is especially the case for many important services, such as coastal protection, nutrient cycling, erosion control, water purification, and carbon sequestration. In recent years, substantial progress has been made by economists working with ecologists and other natural scientists in applying environmental valuation methodologies to assess the welfare contribution of some of these regulating services. The various nonmarket valuation methods used for ecosystem services are essentially the standard techniques that are available to economists. Later on in this article, we discuss the issues that arise in applying these methods in

Figure 2 More detailed version of Figure 1 that emphasizes the economic valuation component.

regulating services. Nevertheless, what makes applying these methods to estimate the value of a nonmarketed regulating service especially difficult is that it requires three important, and inter-related, steps.

The first step involves determining how best to characterize the change in ecosystem structure, functions, and processes that gives rise to the change in the ecosystem regulating service. For example, the change could be in the spatial area or quality of a particular type of ecosystem, such as a mangrove forest, marsh vegetation, or watershed extent. It could also be a change in a key population, such as fish or main predator. Alternatively, the change could be due to variation in the flow of water, energy, or nutrients through the system, such as the variability in tidal surges due to coastal storm events or the influx of organic waste from pollution upstream from estuarine and coastal ecosystems.

The second step requires tracing how the changes in ecosystem structure, functions, and processes influence the quantities and qualities of ecosystem regulating service flows to people. Underlying each ecosystem service is a range of important energy flow, biogeochemical, and biotic processes and functions (Naem *et al.*, 2009). For example, water purification by seagrass beds is linked to the ecological processes of nutrient uptake and suspended particle deposition. However, the key

ecological process and functions that generate an ecosystem service are in turn controlled by certain abiotic and biotic components that are unique to each ecosystem's structure. The various controlling components that may affect nutrient uptake and particle deposition by seagrass ecosystems include seagrass species and density, nutrient load, water residence time, hydrodynamic conditions, and light availability. Only when these first two steps are completed is it possible to conduct the final step, which involves using an existing economic valuation method to assess the impact on human well-being that results from the change in ecosystem goods and services.

Despite the progress made in improving the application of environmental valuation methodologies to nonmarket ecosystem regulating services, a number of important challenges still arise in applying these methods. To aid our subsequent discussion of valuation issues, it is useful to look at a more detailed version of Figure 1 that emphasizes the economic valuation component of the latter diagram (see Figure 2).

Valuing Nonmarket Regulating Services

As indicated in Figure 2, there are a number of different ways in which humans benefit from, or value, ecosystem goods, and

Table 3 Various nonmarket valuation methods applied to ecosystem services

<i>Valuation method</i>	<i>Types of value estimated</i>	<i>Common types of applications</i>	<i>Ecosystem services valued</i>
Travel cost	Direct use	Recreation	Maintenance of beneficial species, productive ecosystems, and biodiversity
Averting behavior Hedonic price	Direct use Direct and indirect use	Environmental impacts on human health Environmental impacts on residential property and human morbidity and mortality	Pollution control and detoxification Storm protection; flood mitigation; maintenance of air quality
Production function	Indirect use	Commercial and recreational fishing; agricultural systems; control of invasive species; watershed protection; damage costs avoided	Maintenance of beneficial species; maintenance of arable land and agricultural productivity; prevention of damage from erosion and siltation; groundwater recharge; drainage and natural irrigation; storm protection; flood mitigation
Replacement cost	Indirect use	Damage costs avoided; freshwater supply	Drainage and natural irrigation; storm protection; flood mitigation
Stated preference	Use and nonuse	Recreation; environmental impacts on human health and residential property; damage costs avoided; existence and bequest values of preserving ecosystems	All of the above

Source: Adapted from Table 3-3 in National Research Council (2005) *Valuing Ecosystem Services: Toward Better Environmental Decision Making*. Washington, DC: The National Academies Press.

services. The first distinction is between the *use values* as opposed to *nonuse values* arising from these goods and services. Typically, use values involve some human “interaction” with the environment whereas nonuse values do not, as they represent an individual valuing the pure “existence” of a natural habitat or ecosystem or wanting to “bequest” it to future generations. Direct use values refer to both consumptive and non-consumptive uses that involve some form of direct physical interaction with environmental goods and services, such as recreational activities, resource harvesting, drinking clean water, breathing unpolluted air, and so forth. Indirect use values refer to those ecosystem services whose values can only be measured indirectly, since they are derived from supporting and protecting activities that have directly measurable values. For example, for wetlands, the indirect use values associated with ecosystems services include coastal protection, erosion control, flood protection, water purification, carbon sequestration, maintenance of temperature and precipitation, and habitat support for fishing, hunting, and foraging activities outside the wetlands.

It is clear that many regulating services, such as those listed in [Table 2](#), are mainly associated with indirect use values. These are some of the most difficult values to estimate. [Table 3](#) indicates the various nonmarket methods that can be used for valuing ecosystem goods and services. As shown in the table, the methods used are essentially the standard nonmarket valuation techniques that are available to economists. However, the application of nonmarket valuation to ecosystem goods and services is not without difficulties. Although it is beyond the scope of this review to discuss in detail the advantages and the shortcomings of the different methods and their application, we can summarize some of the key issues (for further elaboration on these issues, see [Barbier, 2007](#); [Barbier et al., 2009](#); [Bateman et al., 2011](#); [EPA, 2009](#); [Hanley and Barbier, 2009](#); [Mendelsohn and Olmstead, 2009](#); [National Research Council, 2005](#)).

Firstly, the application of some of the valuation methods listed in [Table 3](#) is often limited to specific types of ecological

goods and services. For example, the travel cost method is used principally for those environmental values that enhance individuals’ enjoyment of recreation and tourism; averting behavior models are best applied to the health effects arising from environmental pollution. Thus, these valuation methods are best suited to estimating direct use values. These methods are unlikely to be used to value regulating services, unless of course such services have a direct impact on human welfare, such as through reducing pollution that affects human health or recreational activities. Similarly, hedonic wage and property models are used primarily for assessing work-related environmental hazards and environmental impacts on property values, respectively. These hedonic methods can only be applied to valuing regulating services if they influence work-related hazards or property values.

In contrast, stated-preference methods, which include contingent valuation methods and choice modeling, have the potential to be used widely in valuing ecosystem goods and services. These valuation methods share the common approach of surveying individuals who benefit from an ecological service or a range of services, in the hope that analysis of these responses will provide an accurate measure of the individuals’ willingness to pay for the service or services. In addition, stated-preference methods can go beyond estimating the value to individuals of single and even multiple benefits of ecosystems and in some cases elicit nonuse values that individuals attach to ensuring that a preserved and well-functioning system will be around for future generations to enjoy. For example, a study of mangrove-dependent coastal communities in Micronesia demonstrated through the use of contingent valuation techniques that the communities place some value on the existence and ecosystem functions of mangroves over and above the value of mangroves’ marketable products ([Naylor and Drew, 1998](#)). Similarly, choice modeling has the potential to elicit the relative values that individuals place on different ecosystem services. A study of wetland restoration in southern Sweden revealed through

choice experiments that individuals' willingness to pay for the restoration increased if the result enhanced overall biodiversity but decreased if the restored wetlands were used mainly for the introduction of Swedish crayfish for recreational fishing (Carlsson *et al.*, 2003).

However, as emphasized by the National Research Council (2005), to implement a stated-preference study, two key conditions are necessary:

1. the information must be available to describe the change in an ecosystem in terms of the goods and services that people care about, in order to place a value on those goods and services and
2. the ecosystem change must be explained in the survey instrument in a manner that people will understand and not reject the valuation scenario.

For many of the regulatory services listed in Table 2, one or both of these conditions may not hold. For instance, it has proven very difficult to describe accurately through the hypothetical scenarios required by stated-preference surveys how changes in ecosystem processes and components affect ecosystem regulatory functions and thus the specific benefits arising from these functions that individuals value. If there is considerable scientific uncertainty surrounding these linkages, then not only is it difficult to construct such hypothetical scenarios but also any responses elicited from individuals from stated-preference surveys are likely to yield inaccurate measures of their willingness to pay for ecological services (Bateman *et al.*, 2009). Valuation workshop methods may, however, help in terms of conveying information about complex ecological goods and investigating the effects on people's values of scientific uncertainty about linkages within the system (Christie *et al.*, 2006).

In contrast to stated-preference methods, the advantage of PF approaches is that they depend on only the first condition, and not both conditions. That is, for those ecological regulatory functions where there is sufficient scientific knowledge of how these functions link to specific ecological services that support or protect economic activities, then it may be possible to use the PF approach to value these services. The basic modeling approach underlying PF methods, also called "valuing the environment as input", is similar to determining the additional value of a change in the supply of any factor input (Barbier, 2007; Freeman, 2003, Chapter 9; McConnell and Bockstael, 2005). If changes in the structure and functions of ecosystems affect the marketed production activities of an economy, then the effects of these changes will be transmitted to individuals through the price system via changes in the costs and prices of the final good and services. This means that any resulting improvements in the resource base or environmental quality as a result of enhanced regulating services lower costs and prices and increase the quantities of marketed goods, leading to increases in consumers' and perhaps producers' surpluses (Freeman, 2003, Chapter 9).

An adaptation of the PF methodology is required in the case where ecological regulatory functions have a protective value, through various ecological services such as storm protection, flood mitigation, prevention of erosion and siltation, pollution control, and maintenance of beneficial species

(Barbier, 2007; McConnell and Bockstael, 2005). In such cases, the environment may be thought of producing a non-marketed service, such as "protection" of economic activity, property, and even human lives, which benefits individuals through limiting damages. Applying PF approaches requires modeling the "production" of this protection service and estimating its value as an environmental input in terms of the expected damages avoided by individuals. However, PF methods have their own measurement issues and limitations when they are used to value ecosystem goods and services.

For instance, applying the PF method raises questions about how changes in the ecological service should be measured, whether market distortions in the final goods market are significant, and whether current changes in ecological services may affect future productivity through biological "stock effects". A common approach in the literature is to assume that an estimate of ecosystem area may be included in the "PF" of marketed output as a proxy for the ecological service input. For example, this is the standard approach adopted in coastal habitat-fishery PF models, as allowing wetland area to be a determinant of fish catch is thought by economists and ecologists to proxy some element of the productivity contribution of this important habitat function (Barbier, 2007; Freeman, 2003, Chapter 9; McConnell and Bockstael, 2005). In addition, market conditions and regulatory policies for the marketed output will influence the values imputed to the environmental input. For instance, in the previous example of coastal wetlands supporting an off-shore fishery, the fishery may be subject to open access conditions. Under these conditions, profits in the fishery would be dissipated, and price would be equated to average and not marginal costs. As a consequence, producer values are zero and only consumer values determine the value of increased wetland area. Finally, a further measurement issue arises in the case where the ecological service supports a natural resource system, such as a fishery, forestry, or a wildlife population, which is then harvested or exploited through economic activity. In such cases, the key issue is whether or not the effects on the natural resource stock or biological population of changes in the ecological service are sufficiently large that these stock effects need to be modeled explicitly. In the PF valuation literature, approaches that ignore stock effects are referred to as "static models" of environmental change on a natural resource production system, whereas approaches that take into account the intertemporal stock effects of the environmental change are referred to as "dynamic models" (Barbier, 2007; Freeman, 2003, Chapter 9).

Finally, measurement issues, data availability, and other limitations can prevent the application of standard nonmarket valuation methods to many ecosystem regulating services. In circumstances where an ecological service is unique to a specific ecosystem and is difficult to value, then economists have sometimes resorted to using the cost of replacing the service or treating the damages arising from the loss of the service as a valuation approach. For example, a number of studies that have attempted to value the storm prevention and flood mitigation services of the "natural" storm barrier function of mangroves, salt marsh, and estuarine ecosystems have used the replacement cost method by simply estimating the costs of replacing these systems by constructing physical barriers to perform the same services.

The replacement cost method can provide a reliable valuation estimation for an ecological service, but only if the following conditions are met: (1) the alternative considered provides the same services; (2) the alternative compared for cost comparison should be the least-cost alternative; and (3) there should be substantial evidence that the service would be demanded by society if it were provided by that least-cost alternative. Unfortunately, very few replacement cost studies of regulating services meet all three conditions (Barbier, 2007; Freeman, 2003; Hanley and Barbier, 2009; McConnell and Bockstael, 2005). One study that does conform to these criteria estimates the value of using wetlands for abatement of agricultural nitrogen load on the Baltic Sea coast of Sweden (Byström, 2000). The replacement value of the wetlands is defined and estimated as the difference between two cost-effective reductions of agricultural nitrogen pollution: one that uses wetlands for nitrogen abatement and one that does not. The results show that the use of wetlands as nitrogen sinks can reduce by 30% the total costs of abating nitrogen pollution from agriculture in Sweden.

However, economists consider that the replacement cost approach should be used with caution, especially as it has a tendency to overestimate values. A comparison of using an expected damage function approach and replacement cost method of estimating the welfare impacts of a loss of the storm protection service due to mangrove deforestation in Thailand confirms that the latter method tends to produce extremely high estimates – almost 4 times greater than even the largest upper-bound estimate of the expected damage function approach (Barbier, 2007). But the expected damage function has its own limitations, especially when households are risk averse, and under such circumstances, can be a poor proxy for the ex ante willingness to pay to reduce or avoid the risk from storm damages (Freeman, 2003).

Another measurement issue for economic valuation is assessing the multiple benefits that arise from large-scale habitats and ecosystems. One approach is simply to account for as many of the important ecosystem values necessary for determining conservation versus development tradeoffs. This approach was used to estimate the benefits arising from a wide range of ecosystem services provided by the Peconic Estuary in Long Island, New York (Johnston *et al.*, 2002). The tidal mud flats, salt marshes, and seagrass (eelgrass) beds of the estuary support the shellfish and demersal fisheries. In addition, bird watching and waterfowl hunting are popular activities. Incorporating PF methods, the authors simulate the biological and food web interactions of the ecosystems to assess the marginal value per acre in terms of gains in commercial value for fish and shellfish, bird watching, and waterfowl hunting. The aggregate annual benefits are estimated to be \$67 per acre for intertidal mud flats, \$338 for salt marsh, and \$1065 for seagrass across the estuary system. Using these estimates, the authors calculate the asset value per acre of protecting existing habits to be \$12,412 per acre for seagrass, \$4291 for salt marsh, and \$786 for mud flats; in comparison, the asset value of restored habitats is \$9996 per acre for seagrass, \$3454 for marsh, and \$626 for mud flats.

A second approach is to develop integrated ecological-economic modeling to determine the complex ecological production underlying multiple ecosystem services, including

regulating services (Barbier, 2011; Nelson *et al.*, 2009; Sanchirico and Springborn, 2011; Tschirhart, 2009). Such an approach has proven useful when one or more wetland habitats contribute to a range of goods and services. This has been especially appropriate for mapping the life-cycle of fish through coral reef–mangrove–seagrass systems to determine the contribution of each habitat to the biological growth and productivity of marine fisheries and to the protection of coastal properties from storm damages (Sanchirico and Springborn, 2011).

Integrated ecological-economic modeling has been combined with economic valuation methods to analyze land-use options in the Willamette Basin, which covers nearly 30,000 km² in central Oregon (Nelson *et al.*, 2009). The analysis shows how three different land-use scenarios for the Willamette Basin affect hydrological services (water quality and storm peak mitigation), soil conservation, carbon sequestration, biodiversity conservation, and the value of several marketed commodities (agricultural crop products, timber harvest, and rural residential housing). Both the baseline and development scenarios generate higher net present value (NPV) over 1990–2050 in terms of rural residential housing, timber production, and agricultural crops (\$15.26 billion and \$15.27 billion, respectively) than the conservation scenario (\$14.78 billion). However, by 2050, the latter scenario clearly conserves more biodiversity, and thus provides more ecosystem services, than the other two landscape scenarios. The NPV of carbon sequestration from 1990 to 2050 is especially large under the conservation scenario (\$1.6 billion) compared with the baseline and development scenarios (\$0.9 billion and \$0.8 billion, respectively). In fact, if these carbon sequestration values are added to the NPV of marketed commodities, then this scenario generates the most monetary value over 1990–2050. The overall conclusion of the study is that if markets for carbon sequestration could be established in the region, payments for sequestered carbon may make it more profitable for landowners to choose conservation over development.

An Example from Thailand

Overcoming measurement issues is critical as the most important role for valuing nonmarket regulatory services is to inform conservation versus development choices concerning ecosystem management. Such valuation is essential for public policy, because often, the *private benefits* arising from such choices are very different from the *public benefits*. Valuation, then, can show this difference explicitly, thus aiding the correct policy decision with regard to developing or conserving ecosystems. In some cases, valuing nonmarket regulatory services can be critical to this decision, as the failure to value these services properly or to ignore them can bias the policy choice significantly. An example of economic valuation applied to mangrove land use in Thailand shows the importance of this role (Barbier, 2007).

Since 1961, Thailand has lost from 1500 to 2000 km² of coastal mangroves or about 50–60% of the original area. Over 1975–1996, 50–65% of Thailand's mangroves were lost to shrimp farm conversion alone. Although declining in recent

years, conversion of mangroves to shrimp farm ponds and other commercial coastal developments continues to be a major threat to Thailand's remaining mangrove areas. Thus, the choice between conserving versus developing mangroves is an important land-use policy decision in Thailand as well as many other tropical countries.

As illustrated in Figure 3, when this decision is made on the basis of the private benefits of commercial shrimp farm areas compared with retaining mangroves, it looks as if the aquaculture option should be preferred. For a typical shrimp farm, the present value of commercial profits is around \$9600 ha⁻¹, whereas the value to local communities of exploiting mangroves directly for a variety of products, such as fuelwood, timber, raw materials, honey and resins, and crabs and shellfish, is only about \$580 ha⁻¹. But this comparison of private benefits is misleading. Many of the conventional inputs used in shrimp pond operations are subsidized, below border-equivalent prices, thus increasing artificially the private returns to shrimp farming. A further problem is that intensive shrimp farming usually lasts for only a short period of time, usually 5 years or even less. After this period, there tend to be problems of drastic yield decline and disease; shrimp farmers then usually abandon their ponds and find a new location. Once the generous subsidies to shrimp farming are accounted for, the actual value of the private benefits of aquaculture, when discounted over the 5-year period of normal operation, amounts to \$1220 ha⁻¹.

However, during their operation, intensive shrimp farming generates substantial water pollution, as the ponds are often

flushed with water that is then discharged into the surrounding environment. The cost of this pollution is estimated to be around \$1000 ha⁻¹ in present value terms. There is also the problem of the highly degraded state of abandoned shrimp ponds after the 5-year period of their productive life. Across Thailand, those areas with abandoned shrimp ponds degenerate rapidly into wasteland, since the soil becomes very acidic, compacted, and too poor in quality to be used for any other productive use, such as agriculture. Rehabilitation of the abandoned shrimp farm site would require treating and detoxifying the soil, replanting mangrove forests, and maintaining and protecting mangrove seedlings for several years. These restoration costs are considerable, and are estimated to be \$9318 ha⁻¹. As indicated in Figure 3, when pollution and restoration costs are included, the *net public costs* of shrimp farming are about \$9100 ha⁻¹.

But there are also additional *public benefits* from mangroves beyond the direct private benefits to local communities from using the resources. Mangroves serve as nursery and breeding habitats for many species of fish that are important to off-shore fisheries. Mangroves also play an important role as natural "storm barriers" to periodic coastal storm events, such as wind storms, tsunamis, storm surges, and typhoons. The present value of mangroves as habitat in support of fisheries is \$987 ha⁻¹, and that for storm protection is \$10,821 ha⁻¹. After adding these two public benefits of mangroves, their value increases to nearly \$12,400 ha⁻¹.

The Thailand mangrove case study illustrates how basing a land-use decision solely on comparing the *private benefits* of

Figure 3 Shrimp farming versus mangrove conservation, Thailand.

conservation versus development options is misleading. The irreversible conversion of mangroves for aquaculture results in the loss of ecological services that generate significantly large economic benefits. In fact, the largest of these public benefits is from a regulating service, the storm protection benefits of mangroves. Any loss of this and other ecosystem services should be taken into account in land-use decisions that lead to the widespread conversion of mangroves, but typically are ignored in private sector calculations. The high restoration costs also reflect the fact that “reversing” mangrove conversion is difficult, and should not always be considered *ex post*. Instead, before the decision to allow shrimp farming to take place, the restoration costs could be treated as one measure of the public costs of converting mangroves irreversibly, and this cost should be deducted from the estimation of the net returns to shrimp aquaculture. Other public costs that occur during the operation of the shrimp farm, such as pollution, should also be included. As the example shows, shrimp farming actually can lead to a large net public cost, whereas conserving the mangroves instead yields a substantial public benefit.

Spatially Variable Ecosystem Services

A common assumption is often made that the “value” of an ecosystem regulating service changes “linearly” with critical habitat variables, such as size (e.g., area). One reason for invoking such an assumption is that little data exist for examining the marginal losses associated with changes in nonlinear ecological functions, making it difficult to value accurately the changes in ecosystem services in response to incremental changes in habitat characteristics (e.g., area). Thus, a “point estimate” for the value of an ecosystem service, in terms of benefits per hectare (ha), is simply multiplied by the total land area of an ecosystem to obtain the value of the service provided by the entire system. If, however, the relationships between ecosystem structure and function are nonlinear, then assuming that the value of an ecosystem service varies linearly with respect to changes in habitat or ecosystem area will mislead management decisions.

The potential problem can be illustrated by revisiting the case study of Thailand mangrove use (see An Example from Thailand and Figure 3) (Barbier *et al.*, 2008). As indicated previously, in this case study, the present value of mangroves for storm protection is estimated at \$10,821 ha⁻¹. The present value of mangroves as habitat in support of fisheries is much lower, at \$987 ha⁻¹, whereas the value to local communities of exploiting mangroves directly for a variety of products, such as fuelwood, timber, raw materials, honey and resins, and crabs and shellfish, is only about \$580 ha⁻¹.

But what if the per hectare values in Figure 3 were used as the basis for a land-use decision to convert a mangrove ecosystem, such as a forest extending 1000 m seaward along a 10 km coastline? The decision as to how much of this forest to convert to shrimp aquaculture may depend critically on whether or not all the mangroves in the 10 km² ecosystem are equally beneficial in terms of coastal storm protection.

For example, suppose it is assumed that the annual per ha values for the various ecosystem benefits are “uniform” across the entire 10 km² land area. Consequently, these benefits are

essentially “linear” with respect to the area of mangroves, that is, to derive the total benefits of an area of mangrove, we simply multiply the “point estimate”, or per unit value, of each benefit times the total number of hectares of a mangrove ecosystem. As a result of this assumption, it does not matter if we are deciding to convert one hectare of mangroves or an entire landscape of 10 km². The outcome would be the same. As shown in Figure 3, since the total of ecosystem benefits (\$12,392 ha⁻¹) exceeds even the private profits of shrimp farming (\$9632 ha⁻¹), then the decision would always be to preserve mangroves.

However, the assumption that the storm protection service is uniform across a mangrove landscape is unlikely to be correct. Not all mangroves along a coastline are equally effective in storm protection. It follows that the storm protection value is unlikely to be uniform across all mangroves either. The reason is that the storm protection “service” provided by mangroves depends on their critical ecological function in terms of “attenuation” of storm waves. That is, the ecological damages arising from tropical storms arise mostly from the large wave surges associated with these storms. Ecological and hydrological field studies show that, where mangroves are effective as “natural barriers”, against storms that generate waves less than 6 m in height, the wave height of a storm decreases quadratically for each 100 m that a mangrove forest extends out to sea. As a study shows, if the nonlinear wave attenuation function for mangroves is used to revise the estimate of storm protection service value for the Thailand case study, then a different land-use outcome emerges (Barbier *et al.*, 2008). Because small losses in mangroves will not cause the economic benefits of storm buffering by mangroves to fall precipitously, the correct land-use decision now is to allow up to 2 km² of mangroves to be converted to shrimp aquaculture and to preserve the remainder of the ecosystem.

The spatial variability of the ecological functions underlying ecosystem regulating services can therefore have an important bearing on the valuation of these services and land-use decisions. A number of ecological functions appear to have this property. For instance, wave attenuation appears to be nonlinear not just for mangroves but for a wide variety of interface coastal habitat, including salt marshes, seagrass beds, nearshore coral reefs, and sand dunes (Barbier *et al.*, 2011). The assumption that underlying ecological functions are spatially uniform is likely to be inaccurate for many other ecosystem regulating services that depend on habitat size, a result that could have important implications for both the valuation of these services across landscapes and the land-use decisions based on such valuations (Barbier, 2011; Brauman *et al.*, 2007; Polasky and Segerson, 2009).

Conclusion

The rapid decline of ecosystems globally has focused attention on the resulting loss in important regulating services (see Table 1). However, our current ecological and economic knowledge of how ecosystems produce these benefits and what values they generate are hampering efforts to improve ecosystem management.

In recent years, considerable progress has been made by economists, ecologists, and other natural scientists in determining the values of some key regulating services. However, there are still many nonmarket services that are insufficiently studied. The difficulty of determining how changes in ecosystem structure, functions, and processes influence the quantities and qualities of ecosystem regulating service flows has prevented further progress in the application of standard nonmarket valuation methods. Overcoming these measurement issues is critical if valuing nonmarket regulating services is to inform policy choices concerning ecosystem conservation versus development.

Integrated ecological-economic modeling has been combined with economic valuation methods to analyze a wide range of ecosystem goods and services, including regulating services. Such methods hold promise for future analysis. But such modeling is not a substitute for understanding better how regulating services arise through the structure and functioning of ecosystems. For example, a common assumption is often made that the value of an ecosystem regulating service is uniform across an ecological landscape. But as the case study from Thailand shows, if wave attenuation by mangroves declines from the seaward edge of a mangrove ecosystem to locations further inland, then the value of the regulating service for the entire landscape will also vary. This can have implications for both the decision as to how much mangroves to convert to alternative economic activities or where to locate such development.

Clearly, more progress is needed in determining how the structure and functioning of ecosystems influence the value of regulating services. In the past, because of the complexity of this task, such services were either improperly valued or simply ignored. What is clear from the limited studies conducted to date is that these services can often prove to be highly beneficial, and to disregard their value can distort important ecosystem conservation and development decisions. As the global decline of ecosystem regulatory services suggests, the failure to value these services properly may be the biggest obstacle to sound management of our remaining ecosystems.

Glossary

Cost-effectiveness analysis (CEA) A kind of economic analysis that allows comparison of the relative effects and costs of two or more actions. Typically the CEA is expressed as the ratio of effects to costs. The effects in CEA do not need to be in monetary values, which is the distinction from cost-benefit analysis (CBA) in which the benefits are assigned with monetary values.

Coupled human and natural systems (CHANS) Integrated systems in which human components interact with natural components.

Ecosystem services Also referred as environmental services, ecological services, or ecosystem goods and services, ecosystem services are the benefits obtained directly and

indirectly from nature, ranging from freshwater, timber, non-timber forest products, through carbon sequestration, water and soil conservation, to tourism and nutrient cycling.

Interactive effect Refers to the effect of an interaction term in statistical analysis, a situation in which the simultaneous effect of two variables on a third one is not additive. In other words, the effect of one variable on another variable depends on a third variable.

Payments for ecosystem services (PES) Also known as payments for environmental services or benefits, PES is a kind of conservation practice that offer incentives (e.g., cash, grain) to participants (e.g., farmers) in exchange for their forgone economic benefits or management efforts to protect one or many types of ecosystem service.

Introduction

China is endowed with immense reserves of natural capital and ecosystem services that flow from it (Ouyang, 2007; Task Force for Eco-Compensation Mechanisms and Policies in China, 2007). Unfortunately, natural capital in many areas has been degraded or lost due to a variety of reasons, such as rapid economic development (Task Force for Eco-Compensation Mechanisms and Policies in China, 2007), increasing human population size (Liu and Diamond, 2005), even faster household proliferation (Liu *et al.*, 2003a), and inappropriate governance (Liu and Diamond, 2008; Liu and Raven, 2010). The resulting degradation and loss of ecosystem services have contributed to large disasters, such as massive flooding in 1998, and other huge impacts on human well-being (e.g., economic losses and harm to human health) (Millennium Ecosystem Assessment, 2005). Having realized these problems, China has developed and implemented a series of large-scale policies to protect and restore natural capital and ecosystem services.

These policies include the Key Shelterbelt Construction Program, Beijing–Tianjin Sandstorm Control Program, Nature Reserve System (NRS) (Liu *et al.*, 2008; Ouyang, 2007), Forest Eco-Compensation Program, Grassland Eco-Compensation Program, Wetland Restoration Program, Natural Forest Conservation Program (NFCP; also known as Natural Forest Protection Program), Grain-to-Green Program (GTGP; also known as the Farm-to-Forest Program or the Sloping Land Conversion Program) (Liu *et al.*, 2008; Ouyang, 2007; Xu *et al.*, 2006a), and Ecosystem Function Zones (EFZs) (Ministry of Environmental Protection and Chinese Academy of

Sciences, 2008). These programs have generated important biophysical effects (e.g., biodiversity conservation; and mitigation of climate change, desertification, droughts, floods, soil erosion, and water runoff) and socioeconomic effects (e.g., poverty alleviation and economic development) (Liu and Diamond, 2005; Liu *et al.*, 2008; Xu *et al.*, 2006a). They also have provided significant benefits, such as carbon sequestration, at the global level (Liu and Diamond, 2005; Liu *et al.*, 2008).

The purpose of this article is to evaluate three major programs – NRS, NFCP, and GTGP – from biophysical and social perspectives. These programs are national in scope and have significant global implications. For example, NFCP and GTGP are among the biggest payments for ecosystem service programs in the world (Liu *et al.*, 2008). For each program, this article offers an overview of background and goals, illustrates their biophysical and socioeconomic effects, and discusses future opportunities, challenges, and needs. The programs are presented in the order of their inception times (1956, 1998, and 1999, for NRS, NFCP, and GTGP, respectively).

NRS

Background and Goal

China is among the world's most biodiverse countries, probably behind only Brazil, Colombia, and Indonesia (Liu and Raven, 2010). In the temperate Northern Hemisphere, China has the richest assemblage of biodiversity. For instance, it

Figure 1 Growth of nature reserves in China. Reproduced from Liu J and Diamond J (2005) China's environment in a globalizing world. *Nature* 435: 1179–1186; Ministry of Environmental Protection (2011) *Bulletin of China's Environmental Status 2010*, and National Bureau of Statistics of China (1985–2010) *China Statistical Yearbooks*. Beijing: China Statistics Press.

contains 16 main biomes according to plant functional types (Liu and Raven, 2010). China has almost 10% of terrestrial vertebrate species (at least 2340 species out of ~25,000 named species worldwide) and ~9% of known vascular plant species (~31,500 out of 350,000 total worldwide) (Liu and Raven, 2010). So far, only a small proportion of species have been recorded. For the eukaryotic species, China may have ~1 million species (out of a global estimate at >12 million (Liu and Raven, 2010)), but <150,000 are actually recorded (Liu and Raven, 2010). However, much of China's biodiversity is under severe threat, such as habitat destruction, environmental pollution, poaching, global climate change, and invasive species (Liu *et al.*, 2003b; Liu and Raven, 2010). For instance, although the number of endangered wild giant pandas is small (~1600) (Viña *et al.*, 2008), the number of remaining wild tigers in China is tiny (~50) ("WWF News," <http://www.worldwildlife.org>).

To protect biodiversity, China has taken a series of actions (Liu *et al.*, 2003b), including both *ex situ* and *in situ* conservation actions. The former include colony relocation (e.g., National Nature Reserves for Milu (*Elaphurus davidianus*) in Shishou City of Hubei Province and in Dafeng City of Jiangsu Province), botanical gardens, zoos, gene banks, germplasm banks, and breeding facilities (e.g., the Breeding Center for Giant Pandas (*Ailuropoda melanoleuca*) in Wolong Nature Reserve in Sichuan Province). The first germplasm bank in China was established in 2007 at the Institute of Botany of the Chinese Academy of Sciences in Kunming. Plans include the collection of 6450 species of plants by the end of 2012 and 19,000 by the end of 2022 ("China Germplasm Bank of Wild Species," <http://www.genobank.org>).

The *in situ* conservation actions include policies prohibiting poaching and gathering, restricting economic development, and establishing the NRS. The NRS is particularly impressive. In the half-century since the first reserve, Dinghushan Nature Reserve, was created in 1956 in Guangdong Province, China has designated 2588 nature reserves (through 2010) (Figure 1). These nature reserves account for 1.49 million km², or ~15% of China's territory (Ministry of Environmental Protection, 2011). The goal of the NRS is to protect biodiversity of all major forms in China.

Distribution

The nature reserves are distributed across the country (Figure 2), but the majority of the land area (~56%) is in western China, concentrated in Qinghai Province as well as Tibet and Xinjiang Autonomous Regions, although the numbers in these regions are relatively small (Wu *et al.*, 2011). The nature reserves vary greatly in size, ranging from 0.01 to 298,000 km². The largest one is Qiangtang Nature Reserve in Tibet, established in 1993 primarily for the protection of Tibetan antelope (*Pantholops hodgsonii*), wild yaks (*Bos mutus*), and their habitat of desert highlands.

Nature reserves are managed at different institutional levels (i.e., national, provincial, city, and county levels). At the national level, there were 319 nature reserves covering 926,756 km² in 2010 (Ministry of Environmental Protection, 2011). These national nature reserves are managed by national government agencies. The majority of them (237) are managed by the State Forestry Administration. The remaining are managed by the Ministry of Environmental Protection (46), State Oceanic Administration (12), Ministry of Agriculture (9), Ministry of Land and Resources (11), Ministry of Water Resources (3), and Chinese Academy of Sciences (1) (Ministry of Environmental Protection, 2010).

Most nature reserves are managed by provincial and county governments. Compared to national nature reserves, provincial and local reserves usually receive less support and are less known. For these reasons, many provincial and local governments have put forth much effort to elevate their reserves to the national level (Xu and Melick, 2007).

Although the vast majority of nature reserves are within a particular administrative or political boundary, some cross those boundaries. At the national level, a number of nature reserves cross country boundaries. For example, China and Russia jointly established the Khanka Lake International Nature Reserve for red-crowned crane (*Grus japonensis*) in 1992. China, Russia, and Mongolia cocreated the Dauria International Nature Reserve in 1994. China and Russia are also considering the establishment of more cross-boundary nature reserves to enhance the conservation of the Siberian tiger (*Panthera tigris*), Amur leopard (*Panthera pardus*), and other rare and endangered species ("Xinhua News," <http://news.xinhuanet.com>).

Biophysical Effects

NRS includes areas for the protection of a variety of geological and paleontological relics, ecosystems, floras, faunas, natural scenery, and natural coastal environments and resources (Ministry of Environmental Protection, 2010). Protected ecosystems include forests, grasslands, desert highlands, inland wetlands, and marine and coastal areas. These ecosystems provide a variety of services such as food and water supply, water and air purification, carbon sequestration, flood and drought regulation, ecotourism and recreation, and refuges for endangered species. Of the total 53 ecoregions represented in China, 29 have more than 10% of their land areas within the current NRS (Wu *et al.*, 2011). Of 502 important bird areas in China, 340 are within the current NRS (Wu *et al.*, 2011). Approximately 81% of China's natural vegetation communities are within at least one nature reserve (Wu *et al.*, 2011).

Figure 2 Spatial distribution of nature reserves in China. The map is provided by Nanjing Institute of Environmental Sciences, Ministry of Environmental Protection of China.

Many nature reserves are established with the primary goal of conserving specific species. For example, there are 63 nature reserves whose primary goal is to conserve the endangered giant pandas (Viña *et al.*, 2010). Fifteen nature reserves have been established for Chinese dove tree (*Davidia involucrata*), seven for Chinese white dolphin (*Sousa chinensis*), and 34 for Chinese giant salamander (*Andrias davidianus*) (Ministry of Environmental Protection, 2010). Besides the focal species, many other species and associated ecosystems in these nature reserves also benefit (Viña *et al.*, 2010).

Since 1997, both biophysical and economic benefits of China's ecosystem services have been assessed (Ouyang and Wang, 1997; Ouyang *et al.*, 1999). However, relatively few rigorous ecosystem services assessments of nature reserves in China have been conducted, and many ecosystem services, such as carbon sequestration, are rarely quantified. An ecosystem service assessment of the Changbaishan Nature Reserve (total size 1965 km²) in Jilin Province, for example, found that annually a total of 105 million m³ of water were stored, 1.2 million tons of carbon were fixed, and 17,021 tons of nutrients were accumulated (Xue *et al.*, 1999).

Owing to inadequate management, the establishment of nature reserves also has caused some negative biophysical effects. In Nuozadu Nature Reserve of Yunnan Province, almost half of its forests were lost due to illegal extraction and open-

access farming with poor management (FCCDP, 1998). Similarly, in Wolong Nature Reserve of Sichuan Province, the panda habitats continued to be lost even after the establishment of the reserve due to rapid population growth and household proliferation, economic development inside the reserve, and extraction of timber and non-timber forest products (Liu *et al.*, 2001). Some studies have also recorded the adverse effects of tourism development (e.g., road construction and hiking) on vegetation, wildlife, and their habitats (Fan *et al.*, 2011; Li *et al.*, 2005; State Forestry Administration, 2006).

Socioeconomic Effects

Globally, the overall benefit–cost ratio of an effective wilderness conservation program is at least 100 (Balmford *et al.*, 2002). In China, taking the Yancheng Biosphere Reserve in Jiangsu Province as an example, a very conservative estimation suggests that the benefit–cost ratio of managing the reserve was 10 without considering the huge revenue from tourism development (Lu *et al.*, 2007). If the benefits of tourism development are taken into account, the benefit–cost ratio would be much larger than 100 for many reserves with tourism (e.g., Jiuzhaigou Nature Reserve in Sichuan Province and Zhangjiajie Nature Reserve in Hunan Province).

The average total annual investment for nature reserves from governments at different levels in China was ~200 million yuan over the past two decades (1 USD=6.8 yuan as of 2010) (Yuan *et al.*, 2008). The total annual investment per square kilometer was approximately US\$53 in the early 2000s, compared to US\$2058 and US\$157 in developed and other developing countries, respectively (Yuan *et al.*, 2008). Moreover, this number continued to decrease with the rapid expansion of the NRS and relatively slow increase in investment. The gap of insufficient funding was filled through revenue-raising activities such as tourism development and the use of natural resources in the reserves (Ouyang *et al.*, 2002; Xu and Melick, 2007; Yuan *et al.*, 2008).

Since 1982, more than 80% of nature reserves in China have launched tourism development programs (Yuan *et al.*, 2008). These programs have produced socioeconomic impacts on local residents, companies, governments, and tourists inside and outside China. First, every year, tourism development produces billions of yuan in revenue for the government. For example, the Zhangjiajie Nature Reserve in Hunan Province received as many as 1.4 million tourists and created as much as 5.6 billion yuan in revenue in 2010 (Statistic Bureau of Zhangjiajie City, 2011). Of those tourists, 555,500 were from outside China. Second, local residents may also benefit from the nature reserves through government subsidies and participation in tourism activities. In Jiuzhaigou Natural Reserve of Sichuan Province, all of the local households have intensively participated in and benefited from tourism business, with the per capita income increasing by more than fourfold after the initiation of tourism (Li *et al.*, 2006b). However, studies have shown that in most reserves, local residents had received only a very small proportion of the produced economic benefits, with the major proportion divided by tourism-related companies and the government (He *et al.*, 2008; Xu and Melick, 2007; Yuan *et al.*, 2008). Besides direct economic benefits, tourism development has also dramatically improved the construction of infrastructure (e.g., roads, hospitals, and hotels), has produced job opportunities, and has changed the income structure of local households and governments (He *et al.*, 2008; Li *et al.*, 2006b; Xu and Melick, 2007; Yuan *et al.*, 2008).

The establishment and management of nature reserves also have some negative socioeconomic consequences such as conflicts over land use, tourism resources, and restrictions of natural resource use between the administrative bureaus of reserves and local residents as well as local governments. For instance, the establishment of many reserves incorporates land that had been allocated to local households or communities under the Contract Responsibility System in the early 1980s; however, many reserves were delimited on maps before determining the property rights and compensation measures for land and associated resources (e.g., forests), which unavoidably triggers conflicts over the use and management of land and associated resources (Miao and West, 2004). In the core zone of Wolong Nature Reserve of Sichuan Province, local residents were prohibited from collecting bamboo shoots and Chinese herbal medicines, which were traditional practices before the establishment of the reserve and constituted a large proportion of their income (Liu *et al.*, 1999).

Future Opportunities, Challenges, and Needs

China continues to expand the NRS. By the end of 2010, China had already achieved its designed goal for 2050 in terms of the number of nature reserves (2500), but had not yet met the goal for 2010 in terms of the percentage of total land area (16.1%, 16.8%, and 18.0% as planned for 2010, 2030, and 2050, respectively) (State Forestry Administration, 2001). Although the rapid increase in quantity is impressive, the total cover area and performance of nature reserves in protecting biodiversity are what really matter. Future expansion efforts should pay special attention to areas rich in endemic biodiversity, areas vulnerable to human activities and climate change, and connections between some existing nature reserves.

Although expansion efforts are needed, it is crucial to invest more resources in existing nature reserves to enhance their management. The current nature reserves are managed by different administrations at different institutional levels, of which the functions and responsibilities are often ambiguous or conflicting. Many reserves are listed only on paper because they are not effectively managed due to the lack of sufficient funding and low engagement of stakeholders (e.g., local residents). Some of these reserves are even “empty” because conservation targets have become extinct since the establishment of the reserves (Li *et al.*, 2010). For example, in Jiuzhaigou Nature Reserve of Sichuan Province, there is no recent evidence of giant pandas, probably due to the skyrocketing number of tourists (State Forestry Administration, 2006). To improve the effectiveness and efficiency of the NRS, it is necessary to rethink its goal, reevaluate and redefine current nature reserves, and establish an integrated administration.

To make the management of nature reserves most effective, it is critical to improve the well-being of local residents. Although tourism has generated much revenue, local residents receive only a small proportion of the economic benefits (He *et al.*, 2008). Thus, economic benefits should be more fairly distributed to local residents in order to provide incentives for local residents to cooperate for effective nature reserve management.

Another aspect for consideration is the potential impacts of global climate change. Although there has been discussion of the potential impacts of global climate change on biodiversity in general, little quantitative work has been conducted in China. Such quantitative research is a foundation to inform the development and implementation of effective climate adaptation strategies.

Information on the biophysical and socioeconomic effects of nature reserves has been largely fragmented so far. Much information (e.g., detailed environmental monitoring and financial data) is held by government agencies and is inaccessible to the public. Thus, systematic and integrated studies as well as timely and transparent information disclosure are needed to better conserve China's biodiversity and secure the provision of ecosystem services.

NFCP

Background and Goal

From the 1950s to 1990s, China's natural forests declined in area by 70% and stocking of natural forests per unit area

Figure 3 Spatial distribution of NFCP and GTGP. Reproduced from Liu J, Li S, Ouyang Z, Tam C, and Chen X (2008) Ecological and socioeconomic effects of China's policies for ecosystem services. *Proceedings of the National Academy of Sciences USA* 105: 9477–9482.

declined by 32% (Zhang *et al.*, 2000). The decline of natural forests was mainly due to the population explosion and soaring demand for timber. Human population in forested areas increased fivefold and timber harvests increased threefold (Zhang *et al.*, 2000). The dramatic decline in the quantity and quality of natural forests resulted in extensive desertification, soil erosion, floods, droughts, carbon emission, and damage to wildlife habitat, and so forth (Liu and Diamond, 2005). In response to failures of previous forestry policies, the severe droughts in 1997, and the massive floods in 1998, the central government decided to implement a series of conservation policies, including NFCP (Liu *et al.*, 2008; Yin, 2009; Zhang *et al.*, 2000).

The goal of the NFCP is to conserve and restore natural forests through logging bans and afforestation because most of the natural forests in China were lost or degraded due to human activities (e.g., logging) and because deforestation was believed to have contributed to the 1998 massive floods (Liu *et al.*, 2008). Specifically, the NFCP aimed to completely ban logging of natural forests in the upper reaches of the Yangtze and Yellow rivers as well as in Hainan Province (Figure 3) by 2000 and substantially reduce logging in other places (Xu *et al.*, 2006a). Furthermore, the NFCP aimed to reduce timber harvests in natural forests from 32 million m³ in 1997 to 12 million m³ in 2003, and to afforest 31 million ha by 2010 through aerial seeding, artificial planting, and mountain closure (i.e., prohibition of human activities such as fuelwood collection and grazing) (Xu *et al.*, 2006a).

Distribution

In 1998, right after the large floods, China started the NFCP pilot study in 12 provinces and autonomous regions/municipalities (Liu *et al.*, 2008). By 2000, the NFCP was expanded to 18 provinces, including the upstream regions of major river systems, especially the Yellow and Yangtze rivers, which had suffered massive ecological degradation (Figure 3). The NFCP target areas are classified into two priorities: the first priority is the state-owned forests, and the second priority is the community-owned forest region. Under different priorities, the levels of financial support from the central government vary, 20% of all costs for the second priority area and 100% for the first priority area (Liu *et al.*, 2007a). In 2011, NFCP was renewed for the 10-year second phase, which also added another 11 counties around Danjiangkou Reservoir in Hubei and Henan Provinces, the water source for the middle route of the South-to-North Water Diversion Project ("China Internet News Center," <http://fangtan.china.com.cn>).

Biophysical Effects

It is a common belief that achieving the NFCP's goal can lead to many biophysical benefits, such as soil erosion reduction, water retention, and flood control. Most indicators of biophysical effects studied so far are immediately observable measures, such as changes in harvested timber, newly forested area, and degree of soil erosion (Liu *et al.*, 2008), partially because it takes time for forests to recover or regenerate. However, some recent

Figure 4 Areas of NFCP by different implementation approaches. Reproduced from State Forestry Administration (2000–2010) *China Forestry Development Report*. Beijing: State Forestry Administration; State Forestry Administration (2001–2009) *Bulletin of Key Forestry Projects*. Beijing: State Forestry Administration, and State Forestry Administration (2006–2010) *Statistical Analysis of National Forestry*. Beijing: State Forestry Administration.

studies have measured changes in forest cover using field data and remotely sensed data (Viña *et al.*, 2011).

Commercial harvesting of natural forests in 13 provinces had stopped, and the unlogged area had amounted to 8.9 million ha by 2000 (Liu *et al.*, 2008). There was a rapid increase in the area under mountain closure and plantation, and the total area had expanded to more than 14 million ha by 2009 (Figure 4). Between 2000 and 2010, NFCP protected 107 million ha forest area and increased forest area by 10 million ha (“China Green Times,” <http://www.greentimes.com>).

The NFCP also has reduced soil erosion. For example, during 2000–2007, sediment concentration in Yellow River had declined by 38%. In Chongqing City alone, the total soil erosion area had reduced in 91% of its administrated counties (“China Green Times,” <http://www.greentimes.com>). In Sichuan Province, from 1998 to 2003, the reduced amount of soil erosion was estimated to be 1.5 billion tons (Zhang, 2006).

Forest cover and wildlife habitat also have been recovering. For instance, since the NFCP started in Wolong Nature Reserve of Sichuan Province, illegal harvesting of natural forests rarely occurs (Bearer *et al.*, 2008) and the habitat of the endangered giant pandas has been recovering (Viña *et al.*, 2007). The NFCP also was helpful in reducing the ecological impact of the devastating 2008 Wenchuan earthquake (Viña *et al.*, 2011). Without the NFCP, much more forest cover would have disappeared due to the earthquake. In the Sichuan Giant Panda Sanctuary and Qinling Mountain Area, the percentage of forest cover has increased since the NFCP was initiated (Li, 2010).

In addition, the NFCP also has had significant ecological effects at the global level. One is increased carbon sequestration. Between 1998 and 2010, the NFCP increased carbon sequestration by an estimated 1.3 billion tons and reduced timber harvest by an estimated 220 million m³ (“China Green Times,” <http://www.greentimes.com>). However, reduced domestic timber production has prompted an increase in the import of timber from other countries (Liu and Diamond, 2005). In 2005, for example, 29.4 million m³ of logs were imported to China, an increase of 10.4% from 2004. Twenty-five percent (or 7.4 million m³) of these logs were from tropical forests.

Socioeconomic Effects

NFCP-related activities received a total commitment of 93.7 billion yuan between 1998 and 2009 (Figure 5). The central government contributed ~80% of this amount, whereas local governments provided the remainder. Most of the money was used to offset economic losses of forest enterprises caused by the transformation from logging to tree plantations and forest management (Liu *et al.*, 2008; Ouyang, 2007). The payments varied with specific tasks: aerial seeding (750 yuan ha⁻¹), artificial planting (3000 and 4500 yuan ha⁻¹ in the Yangtze and Yellow river basins, respectively), regenerating forests through mountain closure (1050 yuan ha⁻¹), and protecting forest (10,000 yuan per worker per 340-ha forest) (Liu *et al.*, 2008; Xu *et al.*, 2006a).

Important measures have been taken to create alternative jobs for people previously in forest enterprises and have largely changed forestry’s economic and employment structure. By the end of 2002 (3 years after NFCP implementation), approximately two-thirds of the 1.2 million logging and processing workers impacted by the NFCP had retired or had been transferred to other sectors (Liu *et al.*, 2008; Xu *et al.*, 2006a). The average income from the tertiary industry (e.g., hotels, restaurants, and entertainment) in 32 forest enterprises jumped from 8.5% in 1997 to 20.1% in 2003 (Liu *et al.*, 2008; Zhang, 2006).

Forest management and plantation farming have become the dominant sources of employment since logging was stopped. For example, the proportion of the staff for forest management in the Chuannan Forestry Bureau and Ebian County of Sichuan Province increased from 0% and 13.1% in 1997 to 52.6% and 76.7% in 2001, respectively (Liu *et al.*, 2005, 2008). Even though the income from forestry in some areas such as Longmin Township in Pengzhou County of Sichuan Province declined, there was an increase in the total income, thanks to income from other sources such as tourism (Qiao *et al.*, 2006).

Government data from 35 key state-owned forest enterprises showed that the gross forestry product had continued to

Figure 5 Investment in NFCP. Reproduced from State Forestry Administration (2000–2010) *China Forestry Development Report*. Beijing: State Forestry Administration; State Forestry Administration (2001–2009) *Bulletin of Key Forestry Projects*. Beijing: State Forestry Administration, and State Forestry Administration (2006–2010) *Statistical Analysis of National Forestry*. Beijing: State Forestry Administration.

decline from 1997 to 2000, and then began to increase in 2001. On average, the annual income of employees within NFCP zones had increased from 4437 yuan in 2000 to 12,645 yuan in 2008. Taking the largest NFCP implementation province, Sichuan Province, as an example, the gross forestry product increased more than 10 times from 1997 to 2009. Annual income from forest farmers also increased more than three times from 2000 to 2009 (“China Green Times,” <http://www.greentimes.com>). However, independent studies by scholars have also found adverse effects of the NFCP. For example, in Sichuan Province, 1172 wood-related industry enterprises and 154,000 employees who depended on income from timber harvesting were negatively affected (Zhou, 2006). The tertiary industry in the Chuannan Forestry Bureau of Sichuan Province suffered a big reduction of income (from 5.0 million yuan in 1997 to 1.1 million yuan in 2001) as a result of reduced wood-related activities (Liu and Zhou, 2005). Approximately 55,000 people in Taijiang County of Guizhou Province had a loss of 6 million yuan, placing some forestry workers below the poverty line (Yang, 2004). Some enterprises could not pay back their loans or pay salaries (Huang, 2005). By 2001, these loans amounted to 12.9 billion yuan, and unpaid salaries reached 860 million yuan.

Local governments also had budgetary burdens because they lost revenue from wood-related industries and were responsible for providing matching funds for the NFCP at the same time (Zhou, 2006). For instance, from 1998 to 2001, the Yanbian County Forestry Bureau of Sichuan Province lost 9.7 million yuan in revenue and had to provide matching funds for NFCP (13% of total investment from the central government) (Liu *et al.*, 2005). In northwestern China, 34.9%, 47.0%, and 59.8% of farmers, livestock grazers, and forest workers, respectively, reported on a survey that their livelihoods had been ruined by the implementation of the NFCP, and the poorer the respondents were, the greater the likelihood they believed they had suffered (Cao *et al.*, 2010).

Future Opportunities, Challenges, and Needs

For the second phase (2011–2020), the NFCP plans to increase forest cover by 5.2 million ha, capture 416 million tons of carbon, provide 648,500 forestry jobs, further reduce soil erosion, and enhance biodiversity (“China Internet News Center,” <http://fangtan.china.com.cn>).

In response to the financial burden on local governments of matching ~20% of central government funds during the first phase, that requirement has been eliminated for the second phase of the NFCP for western provinces. The planned cumulative investment for the second phase is 244.0 billion yuan, with 219.5 billion from the central government and 24.5 billion from local investment (“China Internet News Center,” <http://fangtan.china.com.cn>). Although this adjustment may allow local governments to spend more money on local socioeconomic development, it potentially increases the burden of the central government and the financial risk of the program. The program benefits many stakeholders such as hydropower stations, relevant companies and business sectors, people in the Yangtze and Yellow river basins, and even other countries (e.g., Japan, South Korea, and the US would benefit from the mitigation of sandstorms) (Liu *et al.*, 2008). Thus, market-based mechanisms could be attempted to reduce such financial burdens and risks so as to sustain the program in the long run.

The second phase also increases the payment levels for artificial plantation, mountain closure, aerial seeding, and forest monitoring and management. The payment scheme has been adjusted from a fixed payment level through the year to a payment level that will be adjusted with inflation. However, this planned payment scheme still ignores the spatial heterogeneity of socioeconomic conditions across NFCP implementation areas. Increasing the payment levels simultaneously for all implementation areas may cause overpayment in some areas, whereas some areas still receive unreasonably low payments. To improve the fairness and efficiency of the program,

the payment scheme should consider the spatial heterogeneity of different implementation areas (Chen *et al.*, 2010).

The second phase also emphasizes improvement in people's livelihoods. It plans to improve social insurance (including pension, medical care, unemployment, injury, and maternity), housing conditions, and job opportunities of formal employees in state-owned forest enterprises. Although the increase in NFCP payment levels may also benefit other NFCP-related workers who are not formal employees in state-owned forest enterprises, it will not improve those people's social insurance, housing conditions, and job opportunities. This discriminatory policy not only is unethical but may also induce many social conflicts, because a large number of NFCP-related workers do the same work as, if not more than, formal employees but are not registered as formal employees under the current forestry institutional system.

In addition, many reports on forest recovery have been based only on the statistics of government agencies. More scientifically sound and quantitative studies are needed to more rigorously evaluate the impact of the NFCP on forest quantity and quality changes in both the short and long terms. For example, advanced techniques such as remote sensing are available for comprehensive monitoring (Viña *et al.*, 2011). The complexity of policy implementation in coupled human and natural systems should also be considered (Liu *et al.*, 2007b, c). Instead of assessing various conservation programs separately, further studies should also evaluate their interactive effects (Liu *et al.*, 2008). Interdisciplinary studies are also urgently needed to assess the tradeoffs of NFCP implementation on ecosystem services and human well-being.

GTGP

Background and Goal

Much of China's cropland was on steep slopes, causing serious soil erosion. For example, Yangtze and Yellow river basins had

almost 4.3 million ha of cropland on slopes of $\geq 25^\circ$ (Liu *et al.*, 2008). Although natural forest protection and afforestation efforts of the NFCP are important to reduce soil erosion, another important driving force behind soil erosion is farming on sloping lands. Therefore, a year after the pilot implementation of the NFCP, China initiated the GTGP in 1999. The goal of the GTGP is to convert cropland on steep slopes to forests or grasslands. The main criterion for choosing land plots for inclusion in the GTGP is slope steepness, $\geq 15^\circ$ in northwestern China and $\geq 25^\circ$ in other parts of the country (Uchida *et al.*, 2005).

The major aim of the GTGP was to increase vegetative cover by 32 million ha by 2010, with 14.7 million ha of cropland conversion to forest and grassland and the remaining portion through afforesting barren land and mountain closure (Figure 6) (Xu *et al.*, 2004). It was expected that by 2010 the increase in vegetative cover could control soil erosion across 86.7 million ha and desertification of 102.7 million ha (Yin, 2009). In addition to the primary goal of reducing environmental impacts, the GTGP also aims to alleviate poverty and advance local economic development (Xu and Cao, 2002).

Sloping lands can be converted into ecological and/or economic forests and grasslands, but ecological forests should account for 80% of the total converted land (Liu *et al.*, 2007a). Here, ecological forests refer to forests with high ecological benefits (e.g., carbon sequestration, water and soil retention), while economic forests represent forests with relatively short-term economic returns (e.g., orchards or plantations of trees with medicinal value for commercial use). To offset the lost agricultural revenue due to land conversion, the government provides participating households with a payment in the form of grain and/or cash. The durations of payments are 8 years if the cropland is converted to ecological forests using ecologically important trees, 5 years if it is converted to economic forests using fruit trees, and 2 years if the cropland is converted to grassland (Xu *et al.*, 2004). The payment levels differ by region, with 2250 and 1500 kg of grain, or 3150 and 2100

Figure 6 Areas of GTGP by different implementation approaches. Reproduced from State Forestry Administration (2000–2010) *China Forestry Development Report*. Beijing: State Forestry Administration; State Forestry Administration (2001–2009) *Bulletin of Key Forestry Projects*. Beijing: State Forestry Administration, and State Forestry Administration (2006–2010) *Statistical Analysis of National Forestry*. Beijing: State Forestry Administration.

yuan at 1.4 yuan per kg of grain for each hectare of converted cropland annually in the upper reach of the Yangtze River basin and in the upper and middle reaches of the Yellow River basin, respectively (Liu *et al.*, 2008). Furthermore, GTGP offers farmers additional subsidies (300 yuan ha⁻¹ for miscellaneous expenses every year and 750 yuan ha⁻¹ for seeds or seedlings in the first year) (Feng *et al.*, 2005; Xu *et al.*, 2004).

In 2007, after 8 years of implementation, payment contracts for many GTGP-enrolled lands began to expire. Since the long-term mechanism for addressing the livelihoods of GTGP-participating households had not been established, the central government decided to extend the program for another 8 years. However, the payment levels have been halved (Liu *et al.*, 2008).

Distribution

Compared to the NFCP, the GTGP is broader in geographic scope (Figure 3). The pilot program started in three provinces – Sichuan, Shaanxi, and Gansu – in 1999 (Figure 3). After initial success, it was extended to 17 provinces by 2000 and finally to 25 provinces by 2002 (Figure 3). As Figure 3 shows, the GTGP covers all provinces in western China, which is ~80% of the total area with soil erosion (>360 million ha), including the headwaters of the Yangtze and Yellow rivers (Figure 3). Western China also contains the most desertification-prone area (174 million ha), three quarters of the cropland with a slope >25° (600 million ha), and 60% of the population below the poverty line (Liu *et al.*, 2008; Ouyang, 2007).

Biophysical Effects

Like the NFCP, indicators of the GTGP biophysical effects are often those immediately observable: amount of land converted and afforested, reduction in soil erosion, and reduction in water surface runoff. Ecosystem service changes on large scales, such as flood control, are mainly inferred from changes in immediately observable factors (Liu *et al.*, 2008).

By the end of 2009, the program had cumulatively increased vegetative cover by 25 million ha, with 8.8 million ha of cropland being converted to forest and grassland, 14.3 million ha barren land being afforested, and 2.0 million ha of forest regeneration from mountain closure (Figure 6). The statistics of the State Forestry Administration suggest that forest cover within the GTGP region has increased 2% during the first 8 years (Liu *et al.*, 2008).

Soil erosion and surface runoff have been reduced under GTGP. For example, in Hunan Province, surface runoff was reduced by ~20% and soil erosion declined by 30% from 2000 to 2005 (Li *et al.*, 2006a). Investigations in 14 counties of Sichuan Province indicate that from 1998 to 2003, the area affected by soil erosion declined 10% (Bao *et al.*, 2005). In Zigui County of Hubei Province, over a period of 5 years, converted plots lowered surface runoff by 75–85% and soil erosion by 85–96% in comparison to unconverted cropland (Wang *et al.*, 2007). In the Yellow River basin, it was estimated that surface runoffs would be reduced by 450 million m³ from 2000 to 2020, which is equivalent to 0.76% of the total surface water resources (Jia *et al.*, 2006).

Water resources have been conserved and desertification has been reduced under the GTGP. For example, Minqin

County of Gansu Province saved 516,000 m³ of water in 2003 by reducing irrigation on 4300 ha of GTGP land (Ma and Fan, 2005). In the meantime, desertification has slowed down due to increased vegetation, an increase in air humidity by 15–25%, and a decrease in wind speed on the soil surface by 30–50% of GTGP land (Hou and Zhang, 2002).

The GTGP also enhances soil structure and lowers nutrient loss. In Guizhou Province, GTGP plots had 35–53% less loss of phosphorus than non-GTGP plots (Liu *et al.*, 2002). In Wuyi County of Shaanxi Province, the Chaigou Watershed had 48% and 55% higher soil moisture and moisture-holding capacity in GTGP plots than in non-GTGP plots, respectively (Liang *et al.*, 2006; Liu *et al.*, 2002).

Although vegetation cover has increased due to the GTGP (Liang *et al.*, 2006; Yang, 2006), tree species planted on GTGP land have low diversity. Different regions have different species, but a single or a few species often dominate one region. For example, during 2000–2005 in Henan Province, 40% of GTGP land was planted with poplar, 58% with fruit trees, and less than 2% with other species. In Jiangxi Province, camellia oil was planted in 60% of GTGP land in 2006 (Liu *et al.*, 2008). In addition, some scholars are concerned that afforestation with water-intensive species (e.g., poplar) in the semiarid and arid northwestern regions may not improve the environment; it might even deteriorate it (Cao, 2008).

Socioeconomic Effects

By the end of 2009, the total investment in the GTGP had exceeded 200 billion yuan (Figure 7) and more than 120 million farmers in 32 million households had participated in the GTGP. However, the socioeconomic effects of the GTGP vary from one area to another. In some areas, the vast majority of households were satisfied with GTGP (Hu *et al.*, 2006; Xu and Cao, 2002), which has helped alleviate poverty and reduce income inequality (Li *et al.*, 2011; Uchida *et al.*, 2005; Xu *et al.*, 2006b). It has helped many households shift from farming to nonfarming activities and thus change their income structures (Xu *et al.*, 2010; Zhang *et al.*, 2008). In Wuyi County of Shaanxi Province from 1998 to 2003 alone, 15,000 farmers changed their activities from farming to construction, transportation, and restaurant businesses (Ge *et al.*, 2006). The average household net income for GTGP participants has significantly increased by 75% in Ningxia and 8% in Guizhou (Uchida *et al.*, 2005). After their cropland was converted to GTGP land, many farmers had little to do in rural areas and went to cities to work as migrant workers. For example, in Guizhou Province, the number of migrant workers increased almost 50% over a period of 5 years (from 2.2 million in 2000 to 3.1 million in 2005) (Yang, 2006). In some other areas, farmers complained that participation is not voluntary as the central government claims, and the payment is low compared to agricultural revenue from the land (Xu and Cao, 2002; Xu *et al.*, 2010). In contrast to the optimism of the government, most households expressed concerns about their future livelihoods when the program ceases (Zhang *et al.*, 2008).

Similar to the NFCP, the GTGP has also generated financial difficulties for many local governments because local governments do not receive tax revenues from GTGP land (Huang,

Figure 7 Investment in GTGP. Reproduced from State Forestry Administration (2000–2010) *China Forestry Development Report*. Beijing: State Forestry Administration; State Forestry Administration (2001–2009) *Bulletin of Key Forestry Projects*. Beijing: State Forestry Administration; State Forestry Administration (2006–2010) *Statistical Analysis of National Forestry*. Beijing: State Forestry Administration, and Xu J, Dao R, and Xu Z (2004) Grain to Green Program: Effectiveness, effects of structural adjustment, and economic sustainability. *China Economic Quarterly* 4: 139–162 (in Chinese).

2007; Xu *et al.*, 2006a). Although local governments also receive partial subsidies from the central government, they have to cover other expenses for implementing the GTGP (e.g., monitoring its effectiveness and transporting grain to farmers) (Liu and Zhou, 2005). For example, the local government of Kangding County in Sichuan Province lost 28% of its revenue between 1999 and 2001 (Dong, 2003).

Future Opportunities, Challenges, and Needs

Overall, like the NFCP, the GTGP has led to many accomplishments in terms of both biophysical and socioeconomic effects. However, the program also has induced negative effects on local livelihoods, financial burdens on local governments, and social conflicts between local households and governments over the use of land and associated resources (Miao and West, 2004).

Although the program has been extended for another round, so far there has been no systematic assessment of its effectiveness. Overall assessments were based only on government-reported data with few immediately observable indicators (Liu *et al.*, 2008; Yin, 2009). Considering its tremendous investment and wide distribution, it is crucial to systematically evaluate the biophysical and socioeconomic impacts of this program in both the short and long terms. Although proxies (e.g., slope) could be useful, they may not be sufficient for quantifying erosion severity or other ecological conditions (Yin, 2009). Therefore, further direct measures of environmental conditions, costs, and benefits are important.

The cost-effectiveness of the program can also be enhanced by targeting priority households and lands (Chen *et al.*, 2010; Uchida *et al.*, 2005). This targeting approach is especially useful to balance the environmental and poverty alleviation goals. Currently, in some areas, the GTGP is mandatory rather than voluntary, which has induced enrollment of flat, fertile, and profitable lands, both violating the goals of the program

and harming the program in the long run (Xu and Cao, 2002; Yin, 2009; Zhang *et al.*, 2008).

To improve the performance and ensure the sustainability of the program, greater efforts should be made to improve the program design, engagement, institutional capacity building, and guidance on alternative income sources for participants. Since local communities and households are more able to recognize their needs and constraints, they should be given more power in the program participation, design and implementation. Voluntary participation would avoid enrolling flat and profitable lands and ensure that farmers acquire adequate compensation (e.g., no less than their opportunity costs). A pilot practice may be attempted to decentralize the design and implementation processes to local governments. Decentralization could give local governments more flexibility to adapt to local conditions, reduce the transaction costs for program enforcement, and reduce the financial burden on local governments (Bennett, 2008; Liu *et al.*, 2007a). Furthermore, like many other conservation and development policies in China, the GTGP is implemented separately and the interactive effects between the GTGP and other policies are rarely quantified (Liu *et al.*, 2008). However, for example, the GTGP has had positive impacts on rural household income and rural-to-urban and interior-to-coastal migrations in western China, which implies that it does interact with other policies such as the Western China Development Policy (Li *et al.*, 2011; Zhang *et al.*, 2008).

In addition, the government should improve the provision of alternative income sources for participants to improve their livelihoods in the long run. Although this was a requirement of the GTGP implementation plan at the very beginning, few effective approaches have been taken, and in some places the livelihoods of participants even became worse due to the implementation of the GTGP (Yin, 2009). Remedial actions should also be adopted to offset induced negative impacts on both the environment and the people, especially targeting

priority households such as the poor, minorities, and households with low social capital (Zhang *et al.*, 2008). Another focus area of future research would be how to establish a long-term management mechanism to improve the livelihoods of participants when the program expires.

Concluding Remarks

Despite differences in specific goals and implementation approaches, all three programs – NRS, NFCP, and GTGP – are remarkable ecosystem service policies in terms of investment, scale, and biophysical and socioeconomic effects. Overall, they have dramatically improved China's environmental conditions and ecosystem services, and thus have mitigated the unprecedented ecological degradation in China since the 1950s (Liu, 2010). As these programs continue and ecosystems recover, their ecological impacts will be even larger in the future. Besides the positive biophysical and socioeconomic outcomes, they have also induced some negative consequences. Some of these negative effects (e.g., decrease in revenue due to structural changes in forestry and agriculture) may benefit the government, forest enterprises, farmers, and other stakeholders in the long run. But there are also some common issues in these programs.

The reported effectiveness of these programs is largely based on government-reported data with only a few immediately observable indicators (e.g., implementation area). Rigorous, scientifically sound studies are mostly fragmented and often focus on only one aspect or a few aspects in a small area and for a short period (partly due to data accessibility and costs). Measurements of environmental benefits are mostly based on proxies (e.g., slope of land) rather than on direct observations (e.g., the change in soil erosion). Thus, integrated assessment and direct measurements of environmental conditions are needed to assess these programs.

To maximize the outcomes and minimize costs, the cost-effective targeting approach should be incorporated into the design and implementation processes of the programs (Chen *et al.*, 2010). Decentralization could be attempted to give local governments, communities, and households more autonomy in order to reduce transaction costs, avoid social conflicts, and enhance the performance and fairness of the programs. The targeting and decentralization approaches could also address the spatial heterogeneity across different regions and avoid overpayment for ecosystem services in some areas and underpayment in other areas.

Besides the three programs, some other ecosystem service policies have also been implemented recently. One major policy is the designation of EFZs (Ministry of Environmental Protection and Chinese Academy of Sciences, 2008). Based on the integrated analysis of ecological conditions and problems, evaluation of ecological sensitivity, and levels of importance of ecosystems services, 216 EFZs were identified in China. Of them, 50 national key EFZs, covering 23.4% of China's land surface, were identified on the basis of importance for ecosystem services provision, including biodiversity conservation, water resource conservation, soil maintenance, sandstorm prevention, and flood control (Ouyang, 2007). To maintain and improve ecosystem services in EFZs, the financial payments from the central

government to local governments have been carried out since 2008. In 2008 alone, 6 billion yuan was transferred to 221 counties in EFZs. The total payment increased to 12 billion yuan for 372 counties in 2009 and to 24.9 billion yuan for 451 counties in 2010. Although many biophysical and socioeconomic effects have not yet been assessed, these large amounts of payments in EFZs are expected to improve China's ecosystem services and benefit the rest of the world in the long run.

For these and other payment for ecosystem service programs in China, the central government is the dominant buyer for ecosystem services. With the rapid economic development and increase of financial revenue during the past three decades, the central government can afford to pay for these programs. In the long run, however, if these programs continue and new programs emerge, the financial cost will be very high. Moreover, the government compensation approach also has limitations that are difficult to overcome, including the lack of flexibility, the difficulty in defining payment levels, and high transaction costs (Task Force for Eco-Compensation Mechanisms and Policies in China, 2007). To secure the financial sustainability of current and future programs, it is important to diversify the fund sources by engaging both public and private funds as well as funds from other countries and international organizations (Liu *et al.*, 2008).

The interactive effects among these programs and other conservation and development programs also should be studied. It should be recognized that all programs affect both ecosystem services and human well-being. Thus, a coupled human and natural systems perspective (Liu *et al.*, 2007b, c) would be helpful to understand the complexity of policies and their impacts, and to establish long-term management mechanisms to improve the livelihood of participants in these programs and other ecosystem service policies in both China and many other parts of the world.

Impact of Extreme and Infrequent Events on Terrestrial Ecosystems and Biodiversity

Glossary

Acclimation Reversible physiological or morphological changes an organism experiences in response to changing environmental conditions. Such physiological changes enable the organism to tolerate (or acclimatize to) the new environmental conditions.

Atlantic Multidecadal Oscillation (AMO) A mode of variability occurring in the North Atlantic Ocean and which has its principal expression in the sea surface temperature (SST) field. Controversy exists with regard to its amplitude, and in particular, the attribution of sea surface temperature change to natural or anthropogenic causes, especially in tropical Atlantic areas important for hurricane development.

Bottom up effects Refer to controls on the abundance and/or community structure of organisms that derive from supply of resources (light or nutrients for plants, prey organisms for animals) or from physical factors such as temperature of the environment.

Ecological sorting The process whereby organisms colonize and persist in novel environments, use novel resources or form novel associations with other species as a result of the suites of traits that they carry at the time they encounter the novel condition. It provides an important mechanism whereby new species can fit into an existing community without adaptation.

El Niño Southern Oscillation (ENSO) An occasional shift in winds and ocean currents, centered in the South Pacific region, with worldwide consequences for climate and biological systems.

Functional redundancy Ecosystem property by which more than one species performs a given role so that when one species disappears, the loss of the ecosystem's efficiency as a whole is relatively small; however if several species are lost, the system essentially collapses.

Hysteretic response Phenomenon in which the response of a physical system to an external influence depends not only on the present magnitude of that influence but also on the previous history of the system. Hysteretic responses involve different forward and backwards trajectories of change.

Mast fruiting/seeding The production of many seeds/fruits by a plant every two or more years in regional synchrony with other plants of the same species (community-wide mast fruiting; with other plants of same and different species).

Pacific Decadal Oscillation (PDO) A long-term El Niño-like pattern of Pacific climate variability. While the two climate oscillations ENSO and PDO have similar spatial climate fingerprints, they have very different behavior in time: 20th century PDO "events" persisted for 20–30 years, while typical ENSO events persisted for 6–18 months.

Semelparous An organism producing offspring (flowers and fruits in plants) only once in its lifetime before dying.

Tele-connection Causal link between patterns of weather in two locations, or between two atmospheric occurrences, which are very far apart, such the El Niño Southern Oscillation, where unusually high sea surface temperatures off the west coast of South America can be connected with droughts in Indonesia.

Extremes: A Growing Concern, an Emerging Discipline

The concept that discrete extreme events rather than gradual trends can have disproportionate ecological and societal impacts relative to the temporal scale over which they occur has received increased public and scientific attention in the last few years. In particular, extreme climatic events such as hot spells, megadroughts, hurricanes, and floods involving adverse societal impacts or large economic costs, which often receive extensive media coverage, are increasingly being perceived as indicators of climate change (Easterling *et al.*, 2000a). Within the climate change science community, there is also a consensus based on instrumental and modeling evidence that a set of weather or climate events from the extreme tails of their frequency distributions are becoming and will become more frequent or more intense (or both) in the near future (Easterling *et al.*, 2000b; Meehl *et al.*, 2007). These advances in understanding climatic extremes as key components of the variability in the climate system are accompanied by a growing awareness of the

importance of discrete extreme events (whether driven by climate, geology, or biological forces) in influencing ecological systems at all levels of organization from individuals to entire biomes (Gaines and Denny, 1993; Parmesan *et al.*, 2000; Jentsch and Beierkuhnlein, 2008; Smith, 2011).

An indicator of this emerging subdiscipline is increasing appearance of the term *extreme events* within the ecological literature (Figure 1) as well as special issues or special reviews on the topic appearing in major ecological journals such as *New Phytologist* (160, 2003), *Comptes Rendus Geosciences* (340, 2008), and *Journal of Ecology* (99, 2011).

Dimensions of Driver Extremity: Rarity, Intensity, and Severity

Despite this increased interest, a clear definition of extreme event is still elusive. In climate science, three criteria are often

Figure 1 A bibliometric search of the topic “extreme event/s” using ISI Web of Knowledge in June 2011 yielded in 579 papers published in conjunction with the topics “ecosystems” or “biodiversity” (out of a total of 124,947 papers containing the latter two topics) and 2930 papers published in conjunction with the topic “climate” (out of a total of 154,764 papers containing the topic “climate”). The yearly percent of publications using the topic “extreme event/s” in the ecological literature has nearly doubled every decade, a rate that largely mirrors the pace of growth of the concept within the climatological community.

used to classify events as extreme: rarity, intensity, and severity (Beniston *et al.*, 2007).

Rarity

An event may be classified as extreme when it occurs at a particularly low frequency or rate. For example, the IPCC (2001) defines an extreme weather event as “an event that is rare within its statistical reference distribution at a particular place.” To date, most discussions of extreme events have focused on the statistical description; however, the frequency and likelihood of a given type of extreme event are often poorly known, incomplete, and, in some cases, based on flawed models (Katz and Brown, 1992).

Intensity

Whether or not an extreme event will have important consequences depends in part on the physical characteristics of the event. Irrespective of whether they are rare or not, events characterized by relatively small or large values in these characteristics (i.e., events that have large magnitude deviations from the norm) will more likely have larger impacts compared to events closer to the mean or central tendency. The way intensity is delivered in space (spatial coverage) and time (timing of onset, duration, continuity, and temporal contingency with other events) are likely to determine the magnitude of the event. Although different research groups tend to focus either on temporal or spatial events, these often interact. Events are intense when the ratio between the greatest impact and a typical impact is large or when the magnitude of an extreme event is comparable to the magnitude of all the others taken together. When analyzing the distribution of intensities of

events (e.g., magnitudes of earthquakes or sizes of snow avalanches or wildfires) the frequency often decreases as a power law ($\text{frequency} = [\text{size}]^{-\alpha}$), with α , the slope of a linearized (log–log) regression, falling in the range of 1–2 (Figure 2).

Many natural hazards such as earthquakes, landslides, and forest fires (Sethna *et al.*, 2001; Turcotte *et al.*, 2002) often display these empirical distributions, indicating that the sizes of the rarest and largest (or most intense) event is comparable to the sum of the sizes (or intensities) of all other events (Décamps, 2008). This suggests that under certain critical conditions thresholds are surpassed (e.g., for fire, a threshold drought or fire load condition) that determine the occurrence of very large or intense (extreme) events (Moritz, 1997; Slocum *et al.*, 2010).

Severity or Magnitude

Events are severe whenever they translate into large persistent ecological consequences. The concept is context-dependent because equally intense or equally rare events can translate in different severities in different ecological or evolutionary contexts (e.g., the effects of frosts can be severe in lowland tropical forests but will have little effect at higher latitudes or altitudes). Severe events occur when intensity surpasses some critical threshold. A system may become vulnerable to extreme events whenever intensity values driving variables approach or surpass critical thresholds. The existence and relative position of a critical threshold in turn depends on acclimatory, evolutionary, or ecological sorting processes the system may have experienced that confer the capacity to avoid, resist, or effectively respond to those changes. At the individual level, physiological acclimation ensures that environmental changes are tolerated within a certain normal range of conditions.

Figure 2 Examples of the distributions of natural events displaying power distributions of (a) earthquakes that occurred in 1995 as a function of their magnitude (logarithmic scale; Sethna *et al.*, 2001, reproduced from James *et al.*, with permission from Nature); (b) snow avalanche size distribution (Solé *et al.*, 2001, reproduced from Trends in Ecology); and (c) Amazonian fire size distribution as detected by “scars” on satellite images (Pueyo *et al.*, 2010, reproduced from Ecology Letters, 2010, with permission from Wiley).

At the population level, because extreme events are considered the effective arenas where natural selection takes place (Gutschick and BassiriRad, 2003), former regimes of extreme events may have selected traits to avoid, resist, or circumvent future events. At the level of communities and ecosystems, functional redundancy (more than one species affecting ecosystem properties in similar ways) may provide the capacity to maintain ecosystem functioning (Chapin *et al.*, 1998).

Toward Organism- and System-Based Definitions of Extremity

Extreme climatic or nonclimatic events of interest to ecology are those that impact physiology, development, or evolution of organisms and ultimately affect all levels of ecological organization. Thus, a more unified and operational definition of extremity should emerge from understanding how events shape individuals, populations, and ecosystems. Gutschick and BassiriRad (2003) propose that extreme events are “those episodes during which the acclimatory capacities of organisms are substantially exceeded in rate or magnitude.” Consequently, after the event passes, the organism (or population) exhibits physiological and developmental responses to the environment that are significantly different from normal acclimation. Extremity thus differs from simple stress in that the system carries persistent irreversible aftereffects and displays hysteresis or a lack of capacity to retrace its path as a driving variable varies cyclically. Irreversible or hysteretic responses may result from a driving variable changing at a rate that exceeds acclimation rates or that exceeds an absolute upper or lower limit of acclimation of the organism (Gutschick and BassiriRad, 2003; Figure 3).

Although there is no equivalent description of acclimation or adaptation at higher levels of organization, clearly the range of responses of communities or ecosystems will likely be a function of the “rarity” of the event relative to the set of conditions that the system and its component species have previously experienced (Smith, 2011). An extreme event acts either as an external disturbance which a system can resist or as a disturbance exceeding the resilience of an ecosystem –

that is, its ability to return to its former dynamic state (Bréda and Badeau, 2008). The concept of hysteretic ecological responses (i.e., responses incapable of retracing back its trajectory) may also be useful to define extremity at higher levels of organization such as communities or ecosystems. Events may produce changes that go beyond the capacity of communities to return to the previous state or may make the recovery period extremely long and thus induce community reorganization and ecosystem restructuring.

Types of Extreme Driving Events

Climatic extremes and their ecological consequences have received the most attention because their rate and magnitude of occurrence may be affected by global change. However, extreme events with important ecological responses may also be nonclimatic such as geologic or geomorphic physical disturbances (e.g., earthquakes or landslide-induced root damage) or resource inputs induced by these events (e.g., volcanic ashfalls, large wildfires, Turner *et al.*, 1997). Extreme events can be of biological origin; prominent examples are episodic resource pulses related to reproductive events such as mast fruiting or seeding in plants, periodic irruptions of palatable insects, or episodic frass input during insect outbreaks (Ostfeld and Keesing, 2000). Other resource pulses can be of mixed biological–climatic origin such as storm-related exports of marine mineral nutrient (subsidies) to terrestrial ecosystems (Rose and Polis, 1998), storm-related mass leaf shedding in forests, or rainfall-event driven biomass or seed production in desert ephemeral plants with bottom-up effects on higher trophic levels (Holmgren *et al.*, 2001). Clearly, these pulses are rare and intense, yet the severity in terms of long-term ecological consequences is far from being totally understood.

Large infrequent disturbances such as fires could qualify as extreme events that are generally driven by extreme climate events (e.g., ENSO related-droughts, heat waves) and can have strong long-lasting impacts on ecological systems (Moritz, 1997). Extreme fires are generally related to infrequent large or severe events capable of mobilizing large quantities of

Figure 3 Example of contrasting trajectories of water stress between co-occurring species, depending on acclimation potential. A global change-type drought occurred in southwestern North America during 2001–2003 (Δx) inducing irreversible regional scale die-off of piñon pine trees (*P. edulis*) (a, c) while only producing temporary water stress in juniper (*Juniperus monosperma*) (b, d). Junipers exhibit anisohydric behavior in which low stomatal control allows leaf water potential to frequently decrease as soil water potential decreases. Despite higher variability in leaf water potentials (b), die-off risk is lower due to lower zero-carbon assimilation thresholds (i.e., the water potential at which net assimilation of carbon is zero; approximately -4 MPa) and total stem cavitation threshold (i.e., the water potential at which formation of air bubbles disrupt the xylem water transport, approximately -11 MPa) in juniper. In contrast, piñon pines are isohydric and normally avoid low water potentials by strong stomatal control (a). Piñon pines are more vulnerable to drought because zero-carbon assimilation lies only at approximately -2 MPa and total stem cavitation at approximately -7 MPa. Thus, drought intensity and duration contributed to die-off of piñon pine but not of juniper. Note that with the return to normal hydrological conditions ($-\Delta x$) junipers recovered predrought water potential levels (b) whereas piñon either died or could not recover predrought water potentials (a) (Breshears *et al.*, 2009). Left panel modified from Beisner BE, Haydon DT, and Cuddington K (2003) Alternative stable states in ecology. *Frontiers in Ecology and the Environment* 1: 376–382. Right panel (a–d) reproduced from Breshears DD, Myers OB, Meyer CW, *et al.* (2009) Tree die-off in response to global change-type drought: Mortality insights from a decade of plant water potential measurements. *Frontiers in Ecology and the Environment* 7: 185–189, with permission from ESA.

nutrients, consuming large quantities of aboveground and belowground biomass and organic matter, modifying substrates, resource availability, and the physical environment and thus disrupting population, community, and ecosystem structure and functioning. Finally, biological invasions have been proposed as extreme events (Gutschick and BassiriRad, 2003), yet despite the important impacts on the invaded community, their inclusion is questionable as they remain in the system, chronically affecting it, and thus they may not qualify as discrete events.

Events, Trends, Regime Shifts

Events are naturally discrete in that they involve a certain magnitude of change in drivers and response variables during a certain time, thus defining a certain abruptness (White and Jentsch, 2001). Geologic (e.g., earthquakes), geomorphic (e.g., landslides), hydrologic (e.g., floods), and ecological disturbances (e.g., fire) have in common that they involve a triggering phase, a spreading phase during which large amounts of energy are released and transformed, affecting ecosystems in a

certain magnitude, followed by a slowdown and stopping phase. Climatic events are harder to pinpoint because often there are no clear-cut triggering and slowdown phases, and the distinction between discrete and gradual trends is blurred. White and Jentsch (2001) suggest the use of abruptness (the magnitude to duration ratio) to define events; because magnitude is a measure of the system's response, the definition of events is system- and hierarchy-specific and dependent on the response duration, which in turn is related to the longevity of individuals or the successional speed of communities. Thus, using such relative currency to express abruptness allows comparison among organisms with different life spans or communities with different response speeds (Jentsch *et al.*, 2007).

Large Scale-Drivers of Ecological Events

Although ecologists have historically focused on the effects of locally measured weather components, increasing attention has been recently paid to large-scale patterns of climate variability with marked ecological impacts on interannual and

longer time scales (Stenseth *et al.*, 2003). A growing suite of large-scale indices that reduce complex space and time variability into simple measures or “packages of weather” have become widely available, and, paradoxically enough, these have been often found to be better predictors of ecological processes than local climate itself (Hallett *et al.*, 2004).

One of the most prominent features of large-scale climatic patterns is the ability of spatially synchronizing ecological effects, with examples in most ecosystems of the world, both marine and terrestrial (Stenseth *et al.*, 2003; Holmgren *et al.*, 2001). Mechanistically, synchronization occurs because large-scale teleconnections lead to synchronization of climate variables over mesoscales (10^4 – 10^6 km², Swetnam and Betancourt, 1998) and these same climatic variables have strong bottom-up effects on food-web structure and ecosystem processes. Rainfall changes associated with ENSO in semiarid regions may, for instance, produce a highly synchronic pattern of massive annual plant germination and seed production, inducing rodent outbreaks and predator responses (Lima *et al.*, 2001). The ability of climate to synchronize population dynamics over large geographic areas is also known as the *Moran effect* (Ranta *et al.*, 1997). In forests, El Niño Southern Oscillation (ENSO) events may trigger climatic cues for the synchronization of tree fruit and seed production with cascading effects across the food web and consequences on tree demography. For instance, in dipterocarp forests of Indonesia, community-wide mast fruiting associated with ENSO events triggered regional-scale tree seedling recruitment pulses from large amounts of seeds escaped from predation. At the same time, the population sizes of nomadic vertebrate seed predators increased by two to three orders of magnitude both through reproduction and regional movement (Curran and Leighton, 2000). Similarly, ENSO (El Niño phase)-related grass growth in semiarid regions may, in a lagged fashion, induce large synchronous fires over large areas when an immediate phase reversal to dry La Niña produces desiccation of fuels, thus generating a phase locking between climate oscillations and ecological events (Swetnam and Betancourt, 1990; Kitzberger and Veblen, 1997; Kitzberger *et al.*, 2001).

Because climate variation occurs over spectra of frequencies of climatic events, events may therefore be hierarchically embedded within longer trends or waves of low frequency variation; in other words, high-frequency (e.g., interannual) events may be superimposed over lower-frequency events (e.g., multidecadal). A classic example is variability teleconnected to ENSO embedded in decadal or multidecadal regime shifts between warm and cold ocean states like the Pacific Decadal Oscillation (PDO) or the Atlantic Multidecadal Oscillation (AMO). In this way, the occurrence of extreme climatic and ecological events has been related to the modulating (or contingent) action of high- (e.g., ENSO) and low-frequency events (e.g., PDO, AMO; Jackson *et al.*, 2009). These modulating effects of low and high-frequency climatic modes have been documented as drivers for the occurrence of droughts (Enfield *et al.*, 2001; Gray *et al.*, 2003; McCabe *et al.*, 2004), hurricanes (Kossin *et al.*, 2010), wildfires (Schoennagel *et al.*, 2005; Kitzberger *et al.*, 2007), and events affecting tree demography (Gray *et al.*, 2006).

Dimensions of Extremity in Ecological Responses

The occurrence of an extreme event in a potential driver does not necessarily translate into the occurrence of an extreme ecological response. Understanding when, how, and to what extent extreme events translate into substantial ecological responses is still in its infancy and is the basis of an emerging new field in ecology (Smith, 2011). Authors have considered extreme ecological responses when a set of nonmutually conditions are met.

Response Rarity

Ecological responses are extreme if the alteration in structure or function lies outside the bounds of the “natural or historical range of variability” or the range of critical ecological processes and conditions that have characterized particular ecosystems over specified time periods (Landres *et al.*, 1999). This approach typically uses retrospective data (instrumental, historical, dendroecological, palynological, or other paleoenvironmental proxy) to place the condition of a specific event within the envelope of the previously reconstructed distribution of conditions. Rarity is therefore a function of the capacity of the historical or paleoenvironmental proxy to reconstruct the condition back in time. For example, Suarez and Kitzberger (2010), using dendroecological reconstructions along a rainfall gradient in northern Patagonia showed that the 1998–1999 megadrought induced in the dry eastern forest a concatenation of a massive tree mortality event, growth releases of surviving trees, and a pulse of seedling establishment that was unprecedented during the 20th century. In contrast, in the wet western end of the gradient these processes lay within the range of natural occurrence.

Response Abruptness

In many systems, gradual changes in factors might have little effect until a threshold (commonly referred to as a *tipping point*) is reached at which a large (abrupt) shift occurs that might be difficult to reverse (Scheffer *et al.*, 2001). This extreme ecological response may be the response to a regime shift of the driving factor, a progressive and gradual change that surpasses a threshold. A discrete driver event may surpass a threshold either because the factor increased its variability or because the factor shows low variability but slowly approaches the threshold value and eventually surpasses it (Holling, 1973; Maslin, 2004; Scheffer *et al.*, 2001; Williams *et al.*, 2011; Figure 4).

Response Characteristics

Irreversible, Slow, Delayed, or Hysteretic Recovery

Ecological responses to extreme events often involve permanent irreversible changes in ecosystem structure and function or changes that require long recovery periods to return to prior structural or functional states. For example, large severe infrequent fires that remove adults and propagules of preexisting dominant vegetation in combination with soil erosion, desiccation, and high radiation levels due to removal of dominant cover may determine persistent vegetation shifts or extremely

Figure 4 Abrupt ecological change can occur when (a) a climatic forcing abruptly changes in a steplike fashion, inducing an equally abrupt (but reversible) ecological change from state 1 to state 2 (e.g., sudden reduction of trees versus grasses); (b) when a slow-changing forcing variable eventually surpasses a critical threshold (right vertical line) that produces a major ecological shift; (c) when a forcing variable increases its variability and surpasses in an eventlike fashion a critical threshold that produces an abrupt ecological response; or (d) when a forcing variable exhibits a trend that gradually increases the chances of surpassing a critical threshold. Note that ecological trajectories in cases b–d are hysteretic in that even if the driver returns to previous values, the system remains “trapped” in state 2 as long as the lower (left vertical line) threshold is not reached.

slow regeneration of preexisting vegetation (Allen and Breshears, 1998). Large fire events will have persistent consequences whenever thresholds of fire resistance or propagules’ dispersal capacities are surpassed (Romme *et al.*, 1998).

Discrete events may push the system to a state or condition that precludes tracing back to the stages prior to the event; in other words, the forward and backward responses may not follow the same path (hysteretic response). At the level of organismal responses, hysteresis is the property that differentiates stress acclimation (a reversible response) from responses to extreme events that have surpassed acclimation capacity (Gutschick and BassiriRad, 2003). For example, xylem conductivity, evaporation, and assimilation in plants that suffered drought cavitation (i.e., the disruption under tension of the capillary properties of xylem water due to air-bubble formation) do not follow the same path of recovery (if any) as stressed plants that deal with drought without cavitating. Hysteresis results because the recovery is delayed (e.g., xylem embolism cannot be repaired instantaneously), so the return of the driving variable (e.g., evaporative demand) to its initial value does not instantaneously lead the plant to its initial state through the same forward trajectory. Hysteretic responses at high levels of organization are also common. For example, in semiarid grasslands, experimental rainfall pulses induced hysteretic responses in functional properties of the ecosystem (photosynthesis, respiration and evapotranspiration). Soil wetting and subsequent drying induced changes in below-ground microbial communities that produced soil respiration values different from that observed under the reverse trajectory (i.e., soil drying and subsequent rewetting; Potts *et al.*, 2006; Williams *et al.*, 2009). Severe fires induced by global change type droughts may also show hysteretic properties compared to fires to which the components of the local system are well adjusted (Figure 5).

Response Magnitude

Loss of Key Structuring Species, Changes in Physical Conditions, and Indirect Consequences

Extreme ecological responses may involve the local to regional loss of key structural (e.g., habitat-forming) foundation species due to range shifts, ecotone shifts generated by massive mortality, reproductive and behavioral alterations, migration, and so on. These losses produce concurrent changes in environmental conditions (e.g., light regimes, soil water regimes, etc.) that can permanently or over long periods affect subsequent dynamics (Royer *et al.*, 2011). Climate extremes such as droughts have the potential to rapidly alter vegetation structure and transform associated ecosystem properties. For example, drought and heat anomalies have been implicated in tree die-off on every wooded continent (Allen *et al.*, 2010). An immediate consequence of tree die-off in response to an extreme drought event is the loss of canopy cover (Allen and Breshears, 1998; Royer *et al.*, 2011), resulting in increased near-ground solar radiation, a fundamental driver of ecological processes that in turn impact the physiology, phenology, and reproduction of surviving plants, as well as soil water status and nutrient cycling, and facilitation–competition balances (Stultz *et al.*, 2007). Such microenvironmental changes may impact ecosystems, reducing productivity and diversity (Zhao and Running, 2010), community dynamics, for example, altering forest successional pathways (Suarez and Kitzberger, 2008), or increasing mortality on understory or codominant woody species (Breshears *et al.*, 2005). Lastly, die-off may indirectly impact disturbance regimes (e.g., wildfire, Breshears, 2006; Clifford *et al.*, 2008; insect outbreaks, Floyd *et al.*, 2009), increase invasibility (Kreyling *et al.*, 2008) and accelerate erosion and land degradation rates (Allen and Breshears, 1998).

Figure 5 In northern Patagonia, subalpine forests show hysteretic response in relation to drought and fire. Under normal climatic variability, the alternative state *N. pumilio* forests: (a–d) are dominated by obligate seed-dispersed species and shrublands (*N. antarctica-Chusquea culeou* bamboo; (f) are dominated by fire resprouters and have their own internal fire dynamics of low frequency and low severity in the forest and high frequency in the shrublands. Most shrubland fires stop when they reach the forest boundary, creating sharp edges typical of northern Patagonian landscapes (bottom right photography). Eventually, some fires enter the forest as low-severity fires. However, under conditions of global change-type drought, the fire-sensitive *N. pumilio* forests become flammable and high mortality occurs (e), such as in the unusually large and severe fires that occurred in 1999 (top left photography). Under these conditions *N. pumilio* is unable to disperse or establish due to changes in surface conditions, and shrubs and bamboos, formerly confined to the understory, vigorously resprout and dominate. Return to the forest state has not been documented but may occur at very slow rates and under wetter or colder long-term conditions (Mermoz *et al.*, 2005; Kitzberger *et al.*, 2005). (a–f) Reproduced from Maria Laura *et al.*, with permission from Wiley.

Cascading Effect Across Hierarchical Levels Ultimately Affecting Ecosystem Functions

Extreme climate events can produce physiological responses that exceed acclimation capacity of individuals. If severe enough, these responses may translate into fitness of individuals and population demography (e.g., increased mortality); and if occurring in dominant or key structuring species, they may influence community structure and composition and ultimately produce alteration of ecosystem functions such as primary productivity, water regulation, carbon fixation, and nutrient cycling (Jentsch *et al.*, 2011).

This area of research is related to a relatively new area of manipulative event-based experiments that started in the early 1990s and gained momentum during the last decade (Jentsch *et al.*, 2007). Experiments have the advantage over observational studies of ongoing or past extreme events of allowing adequate replication and control of event characteristics

(magnitude, duration, timing, etc.), thus enabling the analysis of causal relations and the identification of thresholds beyond which individual allocation, population fluctuations, community structure, or ecosystem functions change significantly (Jentsch *et al.*, 2007 and references therein).

Extreme Ecological Responses: Emerging Patterns and Challenges

Extreme Ecological Responses Are Less Common Than Extreme Driver Events

A pattern that is beginning to emerge from experimental studies is that extreme ecological responses are probably much rarer than the occurrence of extremes in potential drivers, and possibly much less frequent than suggested by observational

studies (Smith, 2011). Not all climate extremes lead to ecological extremes, but some ecological extremes (e.g., regime or compositional shifts) may be triggered by small changes in drivers if complex systems are close to tipping points (Van Nes and Scheffer, 2004, ecological surprises). Clearly, extreme ecological events reported from observational studies suffer from being a “filtered” sample of extreme events. Observational studies suffer from two potential biases: in the first, extreme conditions of drivers do not trigger extreme ecological responses and remain unstudied; in the second, cases of extreme events that do not produce significant ecological responses become underreported due to the file “drawer problem” (Bauchau, 1997). Therefore, our view from observational studies may be biased toward equating climate extremes with extreme climatic events (Smith, 2011). However, the apparent resistance of ecosystems observed in experimental studies may not be of such value in the real world because of the following factors.

Too simple systems: Highly simplified experimental systems leave out complexities that reduce resilience (e.g., effects of herbivorous insects, pollinators).

Too small systems: Experimental plots cannot incorporate larger-scale processes such as species range shifts, dispersal of plants, and insects.

System bias: Because of logistic restrictions, event-type experiments have been carried out mostly in grasslands with small-sized and short-lived plant species compared to woody-dominated ecosystems. For example, between 2008 and 2011, 24 data-based publications (22% out of 110 with topic “climate change” AND “experiment*” AND “event*” AND “grassland*” OR “heathland*” OR “tundra*”; Web of Knowledge) appeared, having experimentally manipulated grasslands, heathlands, or tundras in an event-type fashion. In contrast, for the same period, only 10 data papers (7% out of 136 with topic “climate change” AND “experiment*” AND “event*” AND “forest*”; Web of Knowledge) reported on manipulated woody-species dominated ecosystems. Conversely, observational studies are possibly biased toward woody systems because it is in those where the effects – at least in structural, compositional, or demographic terms – are most evident (massive mortality, rapid compositional shifts, sharp structural changes).

Historic blindness: Unless done on artificial communities where historic effects are controlled, experimental studies suffer from ignoring historic contingencies – for example, prior driver regime that may have acclimated species or the prior occurrence of extreme events or disturbances that may have modified functioning influencing the resistance and resilience in the face of the experimental conditions imposed.

Too short measurement periods: Ecological responses may be slow, lagged, or display long-term feedbacks that delay the most important responses, thus preventing experiments from detecting them. For example, in experimentally manipulated grasslands plots, important shifts in composition still occurred 3 years after the ending of treatments (Buckland *et al.*, 2001). Lagged effects are also very important in systems with long-lived species. In trees, for example, the effects of drought might become evident with important time lags related to complex interactions between physiological stress and mortality agents such as insect and diseases, which may trigger tree mortality

in a lagged fashion (Cherubini *et al.*, 2002; Bigler *et al.*, 2007; Bréda *et al.*, 2006). Single extreme events may have long-lasting effects on the dynamics of plant production due to internal feedbacks. For example, Haddad *et al.* (2002) suggest that a single drought may be the cause of 9-year-long periodic oscillations in productivity of grassland driven by litter-nitrogen productivity feedback effects.

Too simple treatments: Manipulations that only amplify one aspect of an extreme event may not suffice to produce ecological responses. For example, the timing and duration of drought are often more important than the absolute reduction in rainfall. Combinations with other factors (e.g., temperature and drought) are increasingly being incorporated. More complex treatments such as sequences of events are probably more realistic.

Too unnatural treatments or excessive undesired artifacts: Imposing treatments that mimic climate extremes can be a challenging task. For example classic warming artifacts such as open-top chambers by being passive have the problem of producing variable temperature differences, depending on short-term micrometeorological conditions. Moreover, by being partially enclosed they reduce wind speed and increase relative humidity. A solution to this is the use of modulated infrared lamps that instantaneously maintain constant differences between treatment and ambient temperatures (De Boeck and Nijs, 2011).

Weak treatments: Imposed conditions may have not been sufficiently extreme in comparison to what the system may have previously experienced (Smith, 2011).

Extreme Events Can Alter Components but Generally Higher Level Functions Are Maintained by Compensatory Mechanisms

Ecological systems may display a range of responses to climate extremes, from no response to extreme responses, depending on hierarchically complex, context-dependent sets of interacting mechanisms. Single-species reactions cannot be translated directly to the community and ecosystem levels. Extreme events may produce inconsistent functional responses, or no response at all, at higher hierarchical levels, due to complex complementary compensation mechanisms at lower levels. For example, drought has an important effect on the functional performance (e.g., carbon fixation and nutrient cycling) of individual species or the community, but ecosystem properties related to primary production remain remarkably stable. By changing their relative abundance, drought may change the relative strength of competitive and facilitative interactions among different neighboring plant species, thus buffering primary production changes at the community level without changing community composition (Jentsch *et al.*, 2011).

More Species-rich Communities are not Necessarily more Resistant to Extremes

It has been proposed that species richness may be playing a key role in the ability to withstand perturbations while maintaining ecosystem functions (*resistance*). Richer communities may increase the likelihood that some species or set of species with previous low performance will increase their

performance after the perturbation and compensate for others ("insurance hypothesis," Yachi and Loreau, 1999). However, experiments show conflicting results on the role of species' richness modifying resistance. Some drought or drought and heat experiments produced higher absolute biomass loss or plant mortality in species-rich than in species-poor synthesized grassland communities (Pfisterer and Schmid, 2002; de Boeck *et al.*, 2008; Van Ruijven and Berendse, 2010), presumably because more species-rich systems have a greater chance of including species that perform better under unperturbed conditions but worse under drought conditions ("opposite insurance hypothesis," Pfisterer and Schmid, 2002). Other experiments showed increased resistance with higher species richness (Tilman and Downing, 1994) or lack of relationship (Kahmen *et al.*, 2005; Wang *et al.*, 2007). Possible reasons for these inconsistencies are different relationships between species richness and productivity. When productivity and species richness are positively related, more diverse-productive systems suffer more from droughts than less diverse-less productive ones. In contrast, when diversity and productivity are negatively correlated, more diverse-less productive systems are more resistant to drought. Irrespective of their species richness, communities with lower biomass may be more resistant to drought than more productive ones (Wang *et al.*, 2007).

Importance of Ecological Memory, Recurrent Extreme Events, Sequences of Extreme Events, and Compound Effects of Extremes

Both experimental and retrospective studies are beginning to elucidate the importance of recurrent extreme events as opposed to single extreme events in determining the response and recovery of ecosystems. Outcomes from repeated extreme events can be opposite: each single abiotic stress may weaken organisms and reduce resilience of ecosystems, thus resulting in deteriorated performance and a total loss of resilience when the system is affected by recurrent stressful events (Scheffer *et al.*, 2001). Alternatively, organisms are able to acclimate when faced with abiotic stress, revealing phenotypic plasticity as a response to environmental variability and thus conferring increased resilience (Walter *et al.*, 2011).

Support for the first mechanism can be found in long-lived species such as trees that may witness several extreme events during their lives. Forensic reconstructions using tree rings from trees damaged or killed by extreme drought events and comparison with surviving trees suggest the existence of important negative memory effects from previous droughts (Figure 6).

In support of the first mechanism, populations previously weakened by extreme events are *more* vulnerable to future stressing agents such as extreme climatic events (Suarez *et al.*, 2004; Lloret *et al.*, 2004) or pest attacks (Bréda and Badeau, 2008; Figure 4 and references therein). In support of the second mechanism, physiological adjustment to previous drought events (e.g., root or shoot plastic adjustment, Figure 6b; Suarez *et al.*, 2004; photo protection, Walter *et al.*, 2011) have made some systems less vulnerable to subsequent droughts.

Experimental studies of vegetation responses to climate have largely focused on responses to a trend in climate or to a

single extreme event but have largely overlooked the potential for complex responses to specific sequences of extreme events. Recent experiments imposing different ordering of opposite hydrological events (drought–flood) show that species responses were dependent on the sequence of events imposed as well as the presence or absence of an interceding baseline (average) condition between extreme events (Miao *et al.*, 2009). Moreover, ecological responses (plant growth and mortality) to sequences were not simply an additive result of the responses to individual events and are not likely to be predictable *a priori* based on the knowledge of the physiology and distribution of species (Miao *et al.*, 2009).

The importance of sequences of extreme events for ecological responses has been long recognized in retrospective studies that normally reconstruct ecological events and relate them with time series of drivers. Century-long reconstructions of fire regimes and climate suggest that the occurrence of extreme fires in certain forest types where grasses are important is a direct function of a sequence of extremely wet years that stimulate grass growth followed by extremely dry years that desiccate fuels (Swetnam and Betancourt, 1990; Kitzberger and Veblen, 1997). These sequences are often linked to dominant modes of climate variability such as ENSO (a sequence of the wet phase of El Niño followed by the dry phase of La Niña), and thus extreme ecological processes may be synchronized over large areas with dominant modes of variability (Kitzberger *et al.*, 1997). Other examples of ecological events triggered by particular sequences of drivers are establishment pulses of masting plants (i.e., species that have evolved very irregular temporal seeding patterns with extremely high seed production events interceded by periods of low or null seed production). These species generally require an extreme drought to synchronize the massive seed production followed by an abnormally wet period that ensures adequate germination and seedling survival.

This locking to particular sequences of forecastable drivers has important management implications, as it allows some degree of prediction of extreme ecological events (e.g., Kitzberger, 2002) and the prediction of ecological consequences of particular sequences (e.g., flood-drought) that may become common under future climate change (Miao *et al.*, 2009). Finally, compound sequences of extreme events (Paine *et al.*, 1998) composed by climatic and non-climatic events may generate extreme ecological responses. For example, mass flowering events of semelparous bamboos (species that reproduce gregariously once in their lifetimes, after which they die) generate enormous loads of fuels when culms die off. When these events are followed by strong droughts that desiccate fuels, large and severe fires may occur (Keeley and Bond, 1999 and references therein, Veblen *et al.*, 2008).

Importance of Anthropogenic Amplification in producing Extreme Ecological Responses

Global climate change is projected to yield both higher temperatures and increases in the frequency and intensity of extreme events (Easterling *et al.*, 2000b; IPCC, 2001). Moreover, increased temperatures and droughts may act synergistically to produce extreme events. Unique oceanic and circulation

Figure 6 Examples of opposite effects of ecological memory in relation to past drought events. (a) Tree-ring width chronologies from *Nothofagus dombeyi* trees killed during the most recent 1998–1999 extreme drought in northern Patagonia and from trees that survived that drought. Note that whereas tree growth was nearly equal between groups during 1910–1950, after 1956 growth of trees that were later killed during the 1998–1999 drought was 30–50% lower than growth of trees that survived the 1998–1999 drought. This suggests that the fraction of trees that suffered more from the 1956 drought (in terms of reduced growth) were those that during the 1998–1999 drought were finally killed. In contrast, trees that survived the last 1998–1999 drought were not weakened by the previous drought. On the contrary, in the same system and for the same drought events (b), trees that had adjusted to prior drought events by shutting off the top crown, a common syndrome known as *partial crown dieback*, suffered less mortality from the 1998–1999 drought event than trees with large intact crowns (large shoot to root ratios).

conditions that are “ideal” for drought and embedded within a multidecadal warming trend can cause global change-type droughts such as the globally spanning 1998–2002 drought (Hoerling and Kumar, 2004). One of the most prominent examples of extreme ecological responses are massive forest die-off episodes. Although episodic tree mortality may occur in the absence of climate change, it is increasingly evident that under current and future climate changes, forests may become increasingly vulnerable to increased tree mortality rates and

die-off in response to warm droughts (Allen *et al.*, 2010). Examples of these events come from more than just semiarid systems such as the 2002–2003 massive die-off of *Pinus edulis* (piñon pine) woodlands in North America (Figure 2; Breshears *et al.*, 2005). In environments that are not normally considered water-limited, 30–40-m tall *Nothofagus dombeyi* trees died massively during the warm drought event of 1998–1999 that affected northern Patagonia, Argentina (Suarez *et al.*, 2004).

Similarly, the dynamics of eruptive forest herbivores (i.e., defoliating or boring insects that eventually produce outbreaks) is controlled by complex interactions across different hierarchical levels (Raffa *et al.*, 2008), and sometimes both discrete extreme climate events and trends are needed to produce regime shifts. Severe drought reduces tree resistance and can provide the pulse of stressed trees that beetles need to surpass the eruptive threshold, which in complex interaction with the direct effects of warming on beetle survival caused spruce beetle (*Dendroctonus rufipennis*) outbreaks over vast areas of Alaska and the adjacent Yukon Territory during the 1990s (Berg *et al.*, 2006).

Warming may interact with severe fires to lead to extreme ecological responses. For example, in northern Patagonia during extreme droughts such as the La Niña-related 1998–1999 drought, vegetation firebreaks (mesic less flammable vegetation) and topographic firebreaks (ravines or mountain ridges) that normally control fire spread during average climate lifted during droughts, allowing fire events to seep over large sections of the landscape (Mermoz *et al.*, 2005), thus severely affecting fire-sensitive subalpine *Nothofagus pumilio* forests that are unable recolonize under high-radiation and warmer postfire conditions, leading to a shift from subalpine forests to shrublands (Tercero-Bucardo *et al.*, 2007).

Similarly, introduction of exotic species may reduce resilience and induce extreme ecological responses. In northern Patagonia, invasive European hares prefer browsing in the open areas generated by fire rather than under the forest canopy. Therefore, the presence of this novel herbivore strongly reduces the postfire regeneration of the vulnerable slow-growing seedlings of *N. pumilio*, thus shifting the system toward dominance of shrubs that vigorously resprout after fire, rapidly escaping the browsing action of exotic hares (Kitzberger *et al.*, 2005). In Hawaii, the nitrogen-fixing exotic *Myrica faya* actively invades new surfaces created by large-scale volcanic events and initiates a series of changes including the identity of the dominant tree, nutrient cycling, and productivity (Vitousek, 1990).

Other global anthropogenic changes related to land use may cause loss of resilience in the face of extreme events (Bréda and Badeau, 2008). For example, in the Amazon basin, deforestation causes forest fragmentation and increased edge effects, with changes in microclimate and species composition that make them more susceptible to ENSO-related megadroughts (Laurance and Williamson, 2001) and more prone to carry fires in these fire-vulnerable forests (Cochrane, 2001).

Understanding Extreme Events, a MultiPerspective Endeavor

Three different strategies have been used to analyze the role of events in ecology: look back for events, pinpoint particular ongoing events, or artificially impose events. Retrospective approaches take advantage of temporal depth to capture at least a few events, observational studies that actively pinpoint at individual events capture the event naturally in action, and manipulative experiments on natural or synthetic

communities impose conditions to systems that attempt to mimic extreme natural conditions.

Retrospective studies should provide understanding of the long-term statistical distribution of both drivers and responses, which could provide a notion of extremeness of observed or manipulated events. Furthermore, retrospective approaches are providing important insights into the notions of ecological memory, event sequences, compound effects, and anthropogenic amplification. Observational studies deal with extreme events in action in their natural environment. These have the ability to provide clear notions of magnitude as they are the actual evidence of the consequences of extreme events in natural action. By being opportunistic, they generally fail to detect preexisting conditions but are very efficient in monitoring changes related to the event (e.g., surface conditions, structure, composition, functions). Because events operate as natural experiments, any community can be observed, but emphasis has been on woody-dominated ecosystems where changes are more visible because they often imply the mortality of key structural species. Finally, event experiments have the ability to impose precise conditions, modifying intensity, duration, timing, and sequence of events and to incorporate interactive factors. They also have the capacity of modifying the system to explore how diversity, biomass, and other properties affect resistance and resilience in the face of the imposed condition. This approach is rapidly gaining popularity thanks to important technological improvements that reduce undesired artifacts giving more realism to the condition imposed.

Clearly, none of these approaches by itself will provide full understanding of extreme events in ecology (Table 1). Instead, complementarity of approaches will be necessary to better understand the hierarchy of processes involved in responding to extreme drivers and producing extreme responses.

Extreme Events as Drivers of Global Change

The study of ecological responses to global change has traditionally focused on the effects of climatic trends such as gradual warming, precipitation change, and carbon dioxide enrichment. Short, rare departures from average conditions have been generally overlooked, possibly under the assumption that only persistent changes in drivers would lead to persistent ecological changes. Yet persistence of conditions or slow changes in drivers give natural systems the ability to buffer and linearly adjust by means of an array of mechanisms such as physiological acclimation, resource reallocation, population genetic changes, species migration, and gradual changes in community composition. In contrast, when certain conditions or resources fluctuate sharply, they exceed thresholds beyond which the capacity of systems to effectively adjust is surpassed and, even if the driver fluctuation has a short duration, the consequences on ecological systems are severe and long-lasting. What is becoming clear is that the rules under which ecosystems respond to slow changes in average conditions are very different from the rules that drive ecological responses to abrupt driver changes.

Projected global changes suggest that neither of these responses should be ignored as both gradual changes in average

Table 1 Approaches for study extreme events in ecology and their associated capacities to detect dimensions of extremity of drivers and ecological responses as treated in this chapter

	<i>Retrospective</i>	<i>Observational</i>	<i>Experimental</i>
Statistical rarity of driver	Yes	No	No
Intensity of driver	Yes	Yes	No
Severity of driver	Sometimes	Yes	No
Spatial synchronization	Yes	Yes	No
Relationships with large-scale climatic patterns	Yes	Yes	No
Statistical rarity or severity of response	Yes	Overestimated	Underestimated
Response abruptness	Yes	Yes	Yes
Response characteristics	Sometimes	Yes	Yes
Response magnitude	No	Yes	Yes
Measures functional responses	No	Yes	Yes
System oversimplification	No	No	Yes
Accounts for larger processes?	Yes	Yes	No
System bias	No	Woody-biased	Grassland-biased
Captures slow or, lagged responses	Yes	Sometimes	Starting
Can account for timing, duration of event	No	No	Yes
Can account for factor interactions	No	No	Yes
Reveals effects of diversity	No	No	Yes
Reveals effects of memory, recurrence, sequences	Yes	No	Starting
Reveals compound effects	Yes	Yes	No
Reveals anthropogenic amplification	Yes	Yes	No

conditions and increases in extreme event frequency are expected. Moreover, extremes and long-term trends in drivers may be acting together. The joint effect of how gradual changes of baseline conditions and extreme events translate into extreme ecological responses is still far from being understood.

This chapter shows how global change forces *sensu lato* – for example, climatic change, species introductions, land-use changes (Sala *et al.*, 2000) – may be turning systems less resistant and resilient to extreme driver events (e.g., warming trends may stagnate recovery of systems that have suffered from large infrequent disturbances). Warming may also affect the susceptibility of ecosystems to eventual extreme events. Warmer conditions increase susceptibility of systems to suffer the consequences of extreme driver events, such as eruptive beetle outbreaks. Land-use changes, one of the drivers that probably will produce the largest global effects, also probably strongly interact with extreme events to produce substantial ecological responses. Fragmentation, land degradation, and structural simplification all probably decrease resistance to climate extremes such as droughts or drought-related fires by strongly modifying microenvironments, biotic composition, and fuel loads, particularly in structurally complex systems such as rainforests. Loss of genetic, specific, or functional diversity may be another force making ecosystems less resistant and resilient to extremes. However, clearly the relationships between diversity and stability in the context of extreme events are not clear and are probably very system-specific. Operational limitations need to be resolved to generate more experimental work on functional responses to extreme events in systems other than grass-dominated communities. Introduced plants and animals may modify structural and functional recovery of ecosystem that suffered extreme events. More work is needed to understand whether invasion modifies resistance of communities to extremes. It is also unclear if

one of the responses to extremes is loss of resistance to invasions. Anthropogenic atmospheric changes (e.g., CO₂ increases, N deposition) may also be interacting to modify vulnerability thresholds to extremes, but these interacting effects are still poorly understood.

Extreme Events in Ecology

It is increasingly clear that extreme events are the scenarios in which individuals, populations, and communities undergo the most significant physiological, ecological, and evolutionary changes, whereas intervals between events are periods of relative quiescence. Therefore, trying to understand system properties based on long interevent (average) conditions is simply not enough. Yet because extreme events are generally also short and rare, standard experimental ecological research programs lasting a few (random) years of the systems are not likely to capture the events in action but rather the results of past events.

Extreme drivers and extreme events may be part of the natural functioning of ecosystems. It is therefore crucial to advance our understanding and predictive capacity of ecosystems and their services in the context of a more variable global climate. In other words, ecosystems as we conceive of and study them today are most likely the actual consequence of past extreme events. Thus, we need to understand extreme responses as part of the natural variability of ecosystems. Ecosystems may often be dependent on such extreme excursions to sustain some long-term ecological functions. For example, partial crown dieback produced by extreme droughts in northern Patagonia (Figure 6) are a necessary condition to the creation of nesting habitats for the Magellanic woodpecker, a cavity-building bird that sustains a whole guild of cavity-using animals in *Nothofagus* forests (Ojeda *et al.*, 2007).

Large fire events triggered by large fuel accumulations produced by die-off events in semelparous bamboos (*see* Understanding Extreme Events, a Multi Perspective Endeavor) are probably one of the rare but important regeneration opportunities for shade-intolerant, nutrient-demanding, long-lived trees in northern Patagonian forests (Keeley and Bond, 1999, Veblen *et al.*, 2008). Rare (sometimes drought-triggered) mast-seeding or fruiting events are key events not only for the dynamics of plant populations but also for the long-term persistence of consumers such as granivores (Curran and Leighton, 2000). Populations of terrestrial consumers such as coyotes may be dependent on extreme storms that bring marine nutrient pulses into coastal areas (Rose and Polis, 1998).

The pulse of terrestrial resources associated with El Niño precipitation has a profound effect on the ecology of many arid and semiarid terrestrial communities (Holmgren *et al.*, 2001). All these examples suggest that extreme events provide an extra source of resources and conditions that generate ecosystem functions and services that would not be possible in the absence of those events. This not only is conceptually important but also has practical management implications. Extreme events may help managers restore degraded functions – for example, ENSO rainfall events may provide temporal windows of opportunity for the restoration of arid and semiarid systems (Holmgren and Scheffer, 2001), something that would not be feasible during interevent periods.

Our understanding of the causes and consequences of extreme ecological events is still in its infancy. Maturation in this emerging discipline will require a better integration of approaches as well as a broader conception that includes extreme events as part of long-term ecosystem dynamics.

Glossary

Direct land-use change (DLUC) Conversion of land from a noncrop land use to the production of bioenergy crops.

General equilibrium (GE) model Similar to a partial equilibrium (PE) model, but representing all economic sectors, generally in a highly aggregated form. GE models have greater scope but less detail (fewer products in each sector and less detail on each product) than do PE models.

Indirect land-use change (ILUC) Conversion of land from one land-use category to another, induced by the expansion of biofuel production elsewhere.

Life cycle assessment An analytic framework to assess the full environmental impacts of a product or service, from raw material extraction, through production, use, and disposal.

PE model A model of one or a few sectors of the economy that computes an equilibrium state in which supply and demand for each product equilibrate in response to some exogenously defined change, such as a tax, mandate, or loss of supply.

Overview

Biofuels can be produced from virtually any form of biomass, including purpose-grown energy crops, crop and timber residues, and wastes. Commonly used or proposed energy crops include corn, sugarcane, soybeans, rape, wheat, palm, beets, switchgrass, miscanthus, pine, and willow. Just as each crop has different energy content and life cycle consumption of fossil fuel, fertilizers, and other inputs, each crop has a different impact on the overall commodity markets for food, feed, and fiber.

When bioenergy crops are produced on productive cropland, they can displace the production of food, feed, and fiber, driving up the price of the displaced commodities. In response to the price increases, some consumers will switch to lower-priced substitutes and others will simply consume less, while farmers elsewhere will respond by replacing production of the displaced crops. Increasing crop production requires either increasing yields on existing land (intensification) or farming more land (extensification). Intensification involves the use of more inputs, such as fertilizer or water; increasing crop or livestock density; or employing better technology, such as improved genetic varieties. Extensification requires bringing additional land into crop production. If high-carbon value land, such as forest and grassland, is cleared to accommodate the additional production, enough CO₂ and other greenhouse gases (GHGs) may be released from the disturbed soil and biomass to negate the climate benefits of displacing petroleum-based fuels with biofuels. Whether and how much indirect land-use change (ILUC) occurs depends on the relative scale of each of these possible responses.

The production of biofuels from feedstocks that do not compete for land with food, feed, and fiber generally does not induce ILUC. These feedstocks include crop and forestry residues, municipal waste, and crops grown on the so-called “marginal” land that is incapable of supporting economically viable crop production. To the extent that harvesting residues reduces yield, it may result in some land clearing or additional fertilizer use. Although this land clearing and fertilizer use

increases GHG emissions, the effect should be much smaller than that induced by purpose-grown energy crops.

Direct and Indirect Land-Use Change

In the context of biofuels, direct land-use change (DLUC) refers to the conversion of land from some other land-use category to the production of bioenergy crops. DLUC can provide environmental costs or benefits. For example, replacing row crops with perennial grasses will often increase soil carbon sequestration, reduce nutrient and pesticide runoff, and improve biodiversity (Davis *et al.*, 2011).

When crops replace pasture or forest, DLUC can result in substantial GHG emissions. For example, Fargione *et al.* (2008) estimate that converting lowland tropical rainforest in Indonesia and Malaysia to palm biodiesel would result in the release of about 700 Mg ha⁻¹ of CO₂ for more than 50 years, resulting in a “carbon debt” that would take almost 90 years to repay through substitution of biodiesel for petroleum diesel. Only after this carbon debt is balanced would the biofuel serve as an instrument of carbon reduction. Similarly, these authors estimate that draining tropical peatland rainforest to produce palm would release about 3450 Mg ha⁻¹ of CO₂, requiring more than 400 years to repay through fuel substitution. In contrast, production of biofuels from prairie biomass grown on unused or marginal cropland incurs essentially no carbon debt.

In contrast to DLUC, ILUC occurs when bioenergy crops displace other crops, triggering the conversion to cropland of lands, somewhere on the globe, to replace some portion of the displaced crops (Searchinger *et al.*, 2008; Hertel *et al.*, 2010; Al-Riffai *et al.*, 2010). This result occurs because agricultural land is a constrained resource and the demand for food and feed is somewhat insensitive to changes in price (Kløverpris *et al.*, 2008). ILUC is a market-mediated phenomenon: The effects are transmitted through global markets linked by commodity substitutability and the competition for land (Laurance, 2007). Owing to the challenges of modeling global economic behavior, the location and magnitude of

ILUC, and thus the GHG emissions induced by crop-based biofuels, are highly uncertain (Plevin *et al.*, 2010).

Although ILUC emissions are uncertain and likely to remain so due to the assumptions that drive different models, understanding ILUC is critical to understanding whether biofuel production increases or decreases GHG emissions relative to using petroleum-based fuels (Edwards *et al.*, 2010). In most life cycle analyses of the GHG emissions from biofuels, the emission of CO₂ from the combustion of biogenic carbon is considered “carbon neutral” because the biomass was formed from atmospheric CO₂ during photosynthesis (Rabl *et al.*, 2007). However, this carbon neutrality holds only if the biomass production would not have occurred in the absence of biofuel production. If the carbon would have been sequestered and remained so in the absence of biofuel production, releasing this carbon as CO₂ through biofuel combustion is not carbon neutral; it adds to the stock of CO₂ in the atmosphere (Searchinger *et al.*, 2009). To calculate whether biofuel production uses net “additional” biomass requires considering whether feedstock production results in crop displacement and land clearing. So another way of viewing ILUC uncertainty is that if it cannot be proved that ILUC has not occurred, it should not be assumed that a biofuel is carbon neutral (Searchinger, 2010).

Estimating the CO₂ Emissions from ILUC

Although DLUC can be observed and the effects measured, the indirect effects of biofuel expansion are triggered through price changes in global markets and as such are unobservable (Nassar *et al.*, 2011). Estimating ILUC, therefore, requires the use of models. Because the main linkages are economic, economic models have generally been used to estimate ILUC.

Agricultural extensification is recognized as a leading proximate cause of deforestation (Gibbs *et al.*, 2010; Nassar *et al.*, 2011); however, economic effects are only one of the several interacting drivers of land conversion (Geist and Lambin, 2002; Pfaff *et al.*, 2007). Other driving forces include social processes, such as human population growth and migration, and national policies affecting agriculture, land use, and economic development (Geist and Lambin, 2002), as well as cultural, technological, and institutional issues, all interacting in complex relationships (Schaeffer *et al.*, 2005). In this context, deforestation is best understood as an emergent characteristic of a complex system, with a range of proximate and ultimate causes. Given this complexity, the ability to

predict ILUC from a single driver such as increases in commodity prices may be quite limited, and thus a core assumption underlying ILUC modeling is called into question, resulting in model uncertainty that is difficult to quantify.

The economic analyses of ILUC performed to date have assumed that a marginal increase in LUC in any region can be estimated from supply and demand functions for commodities and land, despite the presence of other drivers. Figure 1 illustrates the steps typically used to estimate ILUC emissions from biofuels expansion. When biofuels are produced on former cropland, a cascade of displacements and substitutions may occur. These interactions are estimated using an economic model (step a), which projects changes in economic uses of land, such as cropping, pasture, and forestry. As economic models are not generally spatially explicit, changes in economic uses must be mapped onto specific land cover types (step b). Next, the carbon emissions from conversion of the identified land cover types to its projected new use (step c) are estimated. Finally, for use in biofuel regulations, the estimated ILUC emissions are typically associated with a quantity of biofuel production, resulting in an ILUC emission factor denominated in gram CO₂ per megajoule (step d). Each of these steps is discussed further below.

Estimating Global Market Impacts

There are two main classes of economic models, partial equilibrium (PE) and computable general equilibrium (GE) models, both of which have been applied for estimating the economic and land-use effects of biofuel policies. PE models offer highly detailed representation of one or a few sectors of the economy, such as the agricultural sector; they, however, lack linkages to other sectors of the economy (Kretschmer and Peterson, 2010). GE models, in contrast, are comprehensive in their representation of the economy, reflecting feedback effects among all economic sectors; they, however, offer less detail. For example, a GE model might represent a composite “coarse grains” sector rather than individually representing the characteristics of corn, oats, barley, sorghum, and so on. Computational and data limitations force a tradeoff between detail and scope; combining the scope of GE models with the detail of PE models would result in a model that was computationally intractable. Both approaches have their proponents and detractors; neither is clearly superior for modeling ILUC.

Given the differing modeling approaches, data sets, and parameter choices, models of ILUC emissions have produced widely divergent results. Figure 2 shows the results from several

Figure 1 Schematic of indirect land-use change calculation using economic models.

Figure 2 Ranges of results from models of ILUC emissions induced by expansion of corn ethanol production. Point estimates are indicated by the diamond where applicable. USEPA estimated ILUC emissions that would occur to meet the US Renewable Fuel Standard in each of three years: 2012, 2017, and 2022 (Tyner *et al.*, 2010; Hertel *et al.*, 2010; CARB, 2009; USEPA, 2010; IFPRI = Al-Riffai *et al.*, 2010; Searchinger *et al.*, 2008; Dumortier *et al.*, 2009, and Plevin *et al.*, 2010).

studies modeling the ILUC effects of expanded corn ethanol production. The ranges presented reflect on a variety of approaches to explore the sensitivity of ILUC emissions to various model assumptions. All of the studies shown are based on economic equilibrium modeling except for the Plevin *et al.* (2010) study, which is based on a simplified model parameterized from prior economic model results and thus incorporates model uncertainty in addition to parameter uncertainty.

Mapping Economic Results to Physical Hectares

The GHG emissions resulting from conversion to cropping vary with land cover types and across regions (Fargione *et al.*, 2008). Estimating ILUC emissions, therefore, requires assumptions about the specific land cover types converted as a result of biofuels expansion. As most economic models are not spatially explicit, economic model results must be mapped onto land cover types to predict the emissions from land cover conversion.

One mapping approach relies on survey data or remote sensing to identify the agricultural frontier – the regions in which natural land cover has most recently been converted to agriculture. If the economic model predicts, for example, the conversion of forest to cropland in a region, some models assume that the types of forest converted will resemble the types of forest conversion previously detected in that region. That is, it is assumed that prior land conversion patterns are predictive of future patterns.

For example, Winrock International compared moderate-resolution imaging spectroradiometer (MODIS) satellite images from 2001 and 2007 to detect land-use changes (Harris *et al.*, 2009). However, as noted by the authors, comparing already-classified land cover sets from two time periods can involve high error rates as small differences can be magnified when a

parcel of land changes just enough to change classification between the two data sets. A more accurate – and much more time-consuming – approach would be to compare the two images before classification and to classify the changes directly.

Another approach considered by the European Union's (EU's) Joint Research Center (JRC) uses a spatial allocation model that incorporates land cover trends detected using remote sensing with predictive information such as the distance from existing cropland and the suitability of the land for producing different crops (Hiederer *et al.*, 2010).

Estimating Emissions from Land Cover Change

The magnitude and time profile of emissions from land cover change depend on the type of land cover and the mode of clearing. Burning releases most biomass carbon immediately, mostly as CO₂, but also as black carbon (soot), organic carbon, carbon monoxide (CO), methane (CH₄), and other volatile organic compounds. Nitrous oxide (N₂O) is also generally released on burning biomass.

Estimates of the total CO₂-equivalent emissions from land conversion usually rely on the well-documented Intergovernmental Panel on Climate Change GHG inventory methods, which include estimates of the CO₂ emissions from above- and below-ground biomass, dead organic matter (dead wood and litter), and soil organic matter, as well as non-CO₂ gases from burning above-ground biomass and dead organic matter (IPCC, 2006). Models of ILUC generally also consider some number of years of foregone sequestration of carbon, that is, sequestration presumed to have occurred if not for land cover conversion.

Total emissions are estimated by multiplying the total area in each land cover type by the associated emission factors. Even for a single set of economic model results, different estimates of total emissions will result from different land cover

allocations. For example, the JRC estimated ILUC emissions induced by the EU Renewable Fuel Directive using the MIRAGE GE model. Applying the spatial allocation model (*see* Mapping Economic Results to Physical Hectares) to the MIRAGE resulted in emissions of 168 Mg CO₂ from above- and below-ground carbon stocks, compared with the prior estimates of 43 Mg CO₂ based on the same MIRAGE results and the Winrock land allocation method (Hiederer *et al.*, 2010; Table 25, p. 106). The increased estimate of emissions results from a greater allocation of land-use changes to areas that have a high-carbon carrying capacity (e.g., forests and shrubland) in the Spatial Allocation Model.

Associating ILUC Emissions with a Quantity of Biofuel

When ILUC emissions are included in biofuel regulations, the total emissions are generally associated with a quantity of fuel production to produce a metric in g CO₂e per megajoule. The simplest approach, used by regulators in USA and EU is straight-line amortization, dividing the emissions over 20 (EU) or 30 (US) years of biofuel production (Note that for any given total for ILUC emissions, amortizing over 20, rather than 30, years increases the per-MJ value by 50%). Another approach compares the total cumulative radiative forcing from biofuels to that of gasoline and measures the difference at an arbitrary time in the future (O'Hare *et al.*, 2009). Others have suggested long time horizons, discounting either emission flows (USEPA, 2009) or damages from emissions (Delucchi, 2011). Others have suggested charging for ILUC emissions when they occur (mostly in the first year) rather than amortizing (Melillo *et al.*, 2009).

Food Price Rationing

As noted earlier, one of the effects of biofuel expansion in the resulting competition for land is an increase in food prices. In response to this increase, economic models of ILUC indicate a reduction in food consumption. Because of reduced consumption, less additional land is required than would be if food demand were unchanged. Thus in models of ILUC emissions, the reduction in food consumption appears as a GHG "benefit" (Searchinger *et al.*, 2008; Hertel *et al.*, 2010). One approach to including this social cost in the ILUC factor would be to hold food consumption constant when estimating ILUC. In one such modeling experiment, holding food consumption constant increased the ILUC factor by approximately 40% (Hertel *et al.*, 2010).

Uncertainty in ILUC Emission Estimates

Despite many uncertainties and a wide range of estimates, the consensus from a suite of different economic modeling efforts is that the biofuels expansion results in net emissions from ILUC (Edwards *et al.*, 2010; Plevin *et al.*, 2010). Substantially narrowing the range will be difficult owing to the challenges of accurately modeling the response of the global economy to changes in production. Economic models tuned to historical performance are better suited in projecting small change to the

status quo and less well-suited in modeling the effects of the rapid increase in biofuel production witnessed in the recent history and anticipated in the near future. Another challenge is the lack of spatial reasoning in economic models, requiring a variety of imperfect methods for mapping projected economic activities to specific land cover types.

One important uncertainty not considered in current economic models is the effect of climate change on agriculture. Global increases in extreme weather events suggest that existing models will underestimate future yield in some areas and overestimate yields in far more locations. Based on a probabilistic analysis of climate change and its effects on crop yields, Tebaldi and Lobell (2008) wrote: "[We] estimate the chance that global losses from climate change by 2030 will outweigh gains from CO₂ as unlikely for wheat (<33% chance), likely for barley (>66% chance) and virtually certain for maize (>99% chance). In addition, we estimate larger than 80% chance that net losses for maize will exceed 10% over this relatively short time period." Lobell and Burke (2010) noted that "although most cropping systems exhibit a clearly negative yield response to warming, the precise amount of yield loss per degree warming is often not tightly constrained, either from theory or observations." The longer the analytical horizon used to estimate the climate effects of fuels, the more important it becomes to consider the potential effects of climate on agriculture. An important nexus exists here between the economic models and long-range ecological assessments, such as the Millennium Ecosystem Assessment (<http://www.maweb.org>).

Approaches to Avoiding ILUC

Although estimates of ILUC emissions remain uncertain, ILUC can be reduced, and possibly avoided, by limiting competition between bioenergy feedstocks and other high-demand commodities (Schubert *et al.*, 2010, p. 210). The two main approaches are (1) to ensure that bioenergy crops do not compete with existing food and feed production, and (2) use byproducts of other production systems rather than purpose-grown crops as feedstocks.

Some bioenergy crops can be produced on a so-called "marginal" land that cannot support commercial agriculture. The most beneficial situation from a climate change perspective is to grow perennial grasses, such as switchgrass, miscanthus, or mixed prairie grasses on marginal land, where their deep root systems can enrich soil carbon and improve soil structural properties (Hill *et al.*, 2006; Blanco-Canqui, 2010).

An approach favored by the Roundtable on Sustainable Biofuels (a voluntary certification organization) is to grow bioenergy crops in responsible cultivation areas where the land use from increased bioenergy production is offset locally by intensification, such as increasing cattle stocking density or double cropping, thereby ensuring that the area maintains its prior output while producing energy crops.

The organic portion of municipal solid waste and waste from the food processing and timber industries can also be used to produce biofuels without competing with crops. Estimates of net GHG benefits of using these feedstocks for

biofuels should consider the alternative fate of the biomass. For example, combusting biomass that would have otherwise remained intact in a dry landfill releases additional CO₂ to the atmosphere just as the burning of fossil fuels does. In other cases, the removal of biomass from landfills can reduce methane emissions, resulting in additional GHG reductions.

Crop residues can also be used as a biofuel feedstock. The collection and use of corn stover has been shown to reduce corn yield in subsequent years and to reduce the accumulation of soil carbon (Blanco-Canqui, 2010). Compensating for reduced yield can require extensification, triggering ILUC, or intensification, resulting in additional fertilizer-related N₂O emissions. From a climate change perspective, reducing soil carbon sequestration is equivalent to emitting the carbon. Blanco-Canqui estimates that only 25% of residue can be collected without adversely impacting soil properties, erosion, soil carbon sequestration, and crop production (Blanco-Canqui, 2010). Collecting such a small percentage of stover may not be economically feasible.

Glossary

Afforestation Process of planting trees in areas currently devoid of them. It is done in desert regions and is increasingly common in Europe, where grasslands and pastures are being converted into woodlands and forests.

Agricultural intensification Management of agricultural land to increase yield principally through the use of high-yielding crop varieties, chemical fertilizers and pesticides, irrigation, shorter rotations, larger fields, and mechanization.

Desertification Reduction of the biological potential of land that ultimately leads to the creation of desertlike conditions. It occurs primarily through overuse of marginal lands by humans for agriculture.

Grassland Land that has a vegetation cover dominated by grasses.

Habitat fragmentation Splintering of once contiguous land cover into isolated pieces. Fragmentation happens when habitat is lost from the interior, rather than the edge, of a large block of cover. The resulting habitat patches are sometimes referred to as “habitat islands” and the intervening, converted land is called the “matrix.”

Land cover Physical and biotic character of the earth’s terrestrial surface. Land cover is typically the vegetation (e.g., tropical forest, marsh, desert, cornfield, and shrubland) or human construct (e.g., road, dwelling, and

industrial area) that covers the surface. It may be grossly defined as in the preceding examples, or defined at finer scales (e.g., moist deciduous tropical forest, moist evergreen tropical forest, and dry tropical forest).

Land use The use that humans make of the earth’s terrestrial surface, usually to obtain goods or benefits.

Examples include agriculture, mineral exploration, settlement, natural reserve, and timber production. Land use refers to the dominant human activity that occurs on the earth’s surface, and it often modifies natural characters to change land cover (e.g., replacing native grassland with a cornfield or a road).

Pasture Land used permanently (5 years or more) for herbaceous forage crops, either cultivated or growing wild (wild prairie or grazing land). The dividing line between this category and the category “Forests and woodland” is rather indefinite, especially in the case of shrubs, savannah, etc., which may have been reported under either of these two categories.

Settlement Land used for human habitation, including for the construction of cities, towns, villages, rural settlements, and roads. In a gross sense, settlement is also a land cover when used to refer to the land occupied by the variety of trappings accompanying human living space, including homes, gardens, roads, transportation centers, and industrial areas.

Land use issues concern the processes by which human activities determine land cover. Important issues are agricultural development and intensification, settlement, and extraction of natural resources. In response to human land use, the earth’s land cover has changed from a mosaic of native woodlands, forests, and grasslands to an increasingly impacted mixture of degraded and fragmented native habitats, exotic croplands, and impervious urban surfaces. In the last three centuries, studies suggest that primary forests have declined 20%, natural grasslands and savannas have declined nearly 40%, whereas croplands have increased more than 390%, and pastures more than 460% (Klein Goldewijk, 2001; Klein Goldewijk *et al.*, 2011). Almost 39% of earth’s land surface is transformed into agricultural land and settlements, and an additional 37% of global land without such use has become embedded within agricultural and settled anthromes (Ellis *et al.*, 2010). This article discusses how land use processes have changed through time and how they have caused the natural pattern of land cover to change. This transformation of the planet’s landscape is widely recognized as the primary driver in the current global

loss of biodiversity. Several examples of how land use can influence biodiversity are also considered.

Land Use Issues

Humans obtain food, energy, and shelter from the earth by harvesting natural resources and creating new resources. Both of these activities, especially the creation of new resources by agricultural and industrial actions, modify our environment at a scale unknown for other organisms. Our unparalleled recent success as a species (increasing in total global population size by almost three-fold from 1950 to 2010) and our tremendous ability to modify the environment have allowed us to dramatically transform the earth (Turner *et al.*, 1990). It is estimated that we have transformed or degraded large parts of the earth’s surface, with 20% remaining seminatural and only a quarter left wild (Ellis *et al.*, 2010) and now command 24–32% of the world’s total net primary productivity (Haberl *et al.*, 2007).

Figure 1 The growing global population of humans reduces biodiversity primarily through land use that converts, fragments, and degrades land cover. Human population growth directly affects land use by demanding more food, living space, and natural resources. The specific effects on regional land use are modified by the local human density, local economy, local technology and industrialization, and local political system.

We can conceptualize our effects on the earth's surface by relating our land and resource use to changes in land cover (**Figure 1**). As our population increases, we garner more of the earth to supply our needs. The aspects of the human population that drive changes in land use and resulting land cover are known only in a general way. Population size is obviously an important determinant of our land use. But its importance relative to global affluence, technological capacity, political organization, and social structuring is hotly contested (Turner II *et al.*, 1990; Steffen *et al.*, 2007). Recent insights suggest that population size may directly determine land use at a global scale, but land use locally is determined by the interaction of regional population size, technology, socioeconomic development, industrialization, and policy (see **Figure 1**). Total biological demand for resources and resulting conversion of land cover are determined by the total world population. Where on the planet changes in land use occur is affected by regional population size, technology, policies, conventions, cultural attitudes, and economic forces that discourage or reward land conversion at the local scale (Turner II *et al.*, 1990; Steffen *et al.*, 2007).

Three main land uses are responsible for changes in the earth's land cover. These are (1) agriculture, which includes cultivation, grazing, irrigation, and drainage; (2) extraction of natural resources, primarily for forestry and energy production; and (3) settlement, which we define loosely to include use of land for human settlements ranging from rural villages to cities. Our domination of the earth is clearly reflected by the earth's current land cover, which is primarily a mixture of fragmented and degraded native habitats, exotic croplands and pastures, and settlements (**Figure 2**). This transformation of land cover *per se* is

recognized as the driving force in the loss of biological diversity worldwide. Additionally, land use affects the biosphere indirectly by modifying ecosystem processes and introducing exotic species (Vitousek *et al.*, 1997; Alkemade *et al.*, 2009).

Agriculture

Our agricultural practices have had the greatest influence on the earth's land cover. Before the development of agricultural society, several lines of evidence suggest that the earth was covered with a complex mosaic of forest, woodland, grassland, wetland, tundra, and desert (**Figure 3**). During the last 300 years we have cultivated approximately 11% of the earth's surface (**Figure 4**), and another 24% is currently in use as pasture. This represents an approximate increase of 390–466% since 1700 (Klein Goldewijk *et al.*, 2011). Increases in cultivated land came mostly at the expense of native forests (other than tropical rain forest) and native grasslands (**Figure 5**). We transform the earth by burning and clearing forests, tilling grasslands, draining wetlands, and irrigating arid lands. Agricultural development is responsible for the overwhelming majority of wetland conversion (the global loss of wetlands is not accurately estimated; Meyer and Turner, 1992). The pattern of increasing human population, increasing cropland, and declining forests and grasslands is consistent across the continents except in the USA, Europe, and parts of Asia (Japan, China) where current afforestation is increasing forest and woodland cover (**Figure 6**). This reversal in declining forest area is marked by a first gradual or sudden depletion of the forest resources, later by slow or radical changes in economic structures or organization. These

Figure 2 Current land cover of the world. Human domination is evident by the preponderance of agricultural land cover (cultivated, irrigated, and mosaic lands). lead to a new appreciation of the resources and eventually in an increase in forest area again. This process is also described as the Forest Transition (Mather, 1990).

Although conversion of native land to exotic croplands has slowed, our use of agricultural land has intensified since “the Green Revolution” began in the 1960s (Matson *et al.*, 1997). Agricultural intensification alters land cover by (1) creating highly productive monocultures, (2) diverting water resources, and (3) fueling technology to produce better seeds and more fertilizers, pesticides, and insecticides.

Increasingly intensive use of grasslands for agriculture has resulted in worldwide overgrazing (Figure 7). A direct effect of this is “desertification” or the degradation of land to desertlike conditions. Current estimates indicate that 6% of the earth’s land has been converted to deserts by agricultural activity; nearly 25% of the earth is threatened with desertification (Meyer and Turner, 1992).

Figure 4 Amount of the world under cultivation (cropland) from 1700 to 2000.

Natural Resource Extraction

We extract a variety of resources from the earth for shelter and energy, but at a global scale timber harvest and management have the largest effect among extractive activities on landscape composition and land cover. In 2010, 31% of the earth was forested (4 billion hectares) and 24% (949 million hectares) of forests are currently maintained as plantations or managed for goods and services (FRA2010, 2010). The rate of deforestation shows signs of decreasing, but remains still alarmingly high according to FAO (globally 13 million hectares per year during 2000–2010 period, compared to 16 million hectares per year for the 1990–2000 period). Large-scale planting of trees is significantly reducing the net loss of forest area globally. The net change in forest area in the period 2000–2010 is estimated at –5.2 million hectares per year (an area about the size of Costa Rica), down from –8.3 million hectares per year in the period 1990–2000. During the last decades, Europe, USA, and especially China have planted large areas with forest, the FRA2010 in 2010 reports 25, 26, and 77 million hectares, respectively.

Humans affect all forests by hunting, gathering, recreating, and suppressing fire. However, only fire suppression has the potential to change forest cover type (if successful, it initially slows forest growth by reducing natural thinning but may allow for greater development of late-successional forests by reducing disturbance). Natural resource extraction has a less direct effect on forest cover than does agriculture. Resource extraction modifies the forest by changing seral stage, degrading forest integrity, and fragmenting continuous forest, but is associated with reduced forest cover in only a few locations (southeastern Asia and parts of Africa, Latin America, and India). Agriculture, in contrast, is the primary agent of forest loss, although it also modifies forest function. Some of the forest loss to agriculture is compensated for by maintenance and planting of forest for timber.

Figure 5 Areas occupied by major ecosystems of the world before agriculture (Klein Goldewijk, 2001). Cultivation has mostly affected forests as well as natural grassland/savanna ecosystems. Reproduced from Klein Goldewijk K, Beusen A, van Dreht G, and de Vos M (2011) The HYDE 3.1 spatially explicit database of human induced land use change over the past 12,000 years. *Global Ecology and Biogeography* 20(1): 73–86. doi:10.1111/j.1466-8238.2010.00587.x., with permission from Wiley.

Figure 6 Land use trends and population estimates of major regions of the earth. Land use trends between 1700 and 1980 (closed symbols) are compiled from Richards (1990). After 1950 (open symbols), land use estimates are derived from FAOSTAT (www.fao.org, October 1998). Population estimates in (a) are for Africa only. Panel (f) includes Japan, North and South Korea, and Oceania.

Settlement

The clearing of native land cover and drainage of wetlands for human settlement are the most permanent forms of land conversion. Global population has increased enormously during the last three centuries, from roughly 600 million in AD 1700 to 1.7 billion in AD 1900, 2.5 billion in AD 1950 to 7 billion at present (Klein Goldewijk *et al.*, 2010). This also

had of course consequences for the amount and size of settlements as well, since more and more people live in towns and cities. Currently, the urbanization degree globally is more than 50% (UN, 2009). Despite the large increase in population, the absolute area compared to the total global land surface is still very small. Potere and Schneider (2007) compared six global studies of urban areas and found a range between 276,000–727,000 km², and one outlier of

3524,000 km². That translates to resp. 0.19–0.49% (and outlier 2.4%) of the total land area.

Human settlements typically occupy less than 20% of even the most developed country's area, but this varies widely (Figure 8). Each night we advertise our settlements by turning on lights. Viewing this spectacle from the air provides a striking representation of the degree to which settlements (and some large industrial complexes such as oil and gas drilling sites in Siberia for example) occupy the earth (Figure 9). Human settlement affects nearly all land in Europe, eastern North America, India, and parts of Asia.

Settlement has increased dramatically over the last 300 years as evidenced by the increasing number of large cities (Figure 10). As human populations have grown, we have settled with increasing frequency in urban areas. Today more

Figure 7 Areas of the world affected by overgrazing. This human-induced activity has been identified as one of the major causes for soil degradation. Overgrazed areas are the result of actual removal of biomass by grazing animals and the effect of trampling. The effects are enhanced where too many animals or the wrong kind of animals are grazed. (Reproduced with permission from UNEP (United Nations Environment Programme)/ISRIC (1997) *World Atlas of Desertification*, p. 44. New York: Arnold/John Wiley & Sons.)

than 50% of all humans live in urban areas (primarily in the developed countries), compared to only 14% at the start of the twentieth century (UN, 2009). A result of our increasingly urban life is an increased occupation of area by cities and surrounding lower-density housing and industrial areas (urban and suburban sprawl). This expansion of urban areas in developed countries and the increasing density of large urban areas in the developing tropics are responsible for the severe transformation of parts of the earth's surface.

History Repeats Itself: Past and Future Effects of Land Use on Land Cover

Our transformation of the earth during the last five centuries has proceeded by pioneers expanding frontier settlements in a fairly regular way. When humans settle an area, they open a new frontier where natural resources are abundant, cheap, and readily obtained. As resources are consumed and population increases, we expand our "footprint" on the surrounding land in a series of radiating waves. We transform the land at successively greater distances from a settlement's center by clearing and draining land, extracting resources, and converting land cover to suit our needs (Berry, 1991).

The conversion of land cover was fueled on a global scale by Western European nations and their seaborne pioneers from the 1700s to the early 1900s (Richards, 1990; Klein Goldewijk *et al.* 2011; Williams, 2003). Once the European frontiers were settled, the appetite for amenity and subsistence resources propelled the opening of new frontiers around the world. These frontiers then had to satisfy local and European needs, so resources were harvested with frenzied zeal as opportunities seemed boundless on the frontier. Landscapes were quickly degraded and transformed, and as resources dwindled, the frontier closed and pioneers moved on to new frontiers. However, the old frontier was rarely left to return to a natural state. Rather, a more orderly settlement usually persisted, leading to slower, but more permanent, land transformation. Many of these settlements became new centers in a changing world

Figure 8 Urban areas as expressed as a percentage of land area (excluding water bodies), in selected countries.

Figure 10 Distribution of the sizes of world cities, between 1700 and 1985. The growth rate of cities in the Americas is more rapid relative to that of cities on the European and East Asian continents. The black dots represent cities of varying sizes (•, 200,000–500,000; ●, 500,000–1,000,000; ●, 1,000,000–10,000,000).

economy, thereby broadening the base from which remaining frontiers were exploited.

The global pattern of urbanization over the last 300 years (see **Figure 10**) illustrates the consequences of our opening

and closing the earth's frontiers. New frontiers open in areas increasingly far from Europe, and develop large urban areas as they close. The frontiers of Europe, eastern North America, India, and Asia have closed, leaving dense human settlement

to permanently change land cover. As the remote frontiers of the tropics, mountainous regions, and northern forests and tundras are exploited, settlement will likely increase and land will be transformed to a lasting urban state. Europe can be viewed as a crystal ball for much of the earth's future land use. The forecast is for drastic simplification of a once diverse native land cover to one dominated by settlements, intensive agriculture, and fragmented vestiges of native habitat.

Effects of Land Use on Biodiversity

The current extinction crisis is fueled, at a proximate level, by (1) habitat conversion, (2) habitat fragmentation, and (3) habitat degradation. These are the most common reasons given to explain why modern species are at risk of extinction (IUCN (International Union for the Conservation of Nature), 1996). These three processes are the direct result of our land use and they function as the mechanisms that connect changing land cover to biodiversity (see Figure 1). Conversion of native land cover to agriculture and settlement is unquestionably the main cause of habitat loss on a global scale. This conversion typically occurs in a piecemeal fashion and is associated with extensive road building that fragments habitat as it is being lost. Native and converted habitats that are already utilized by humans are further degraded by agricultural intensification, resource extraction, and recreation.

A recent operational tool for policy support on the global to the national scale is the Global Biodiversity model GLOBIO (Alkemade *et al.*, 2009). It can be used to assess (1) impacts of human-induced environmental drivers on land biodiversity in past, present and future, (2) the relative importance of the environmental drivers, (3) trends under future scenarios, and (4) effects of policy response options, such as climate change mitigation, plantation forestry, and protected areas. GLOBIO has been applied in many integrated, global and regional

environmental assessments (<http://www.globio.info/home>). Figure 11 is an example of an application of GLOBIO from the OECD Environmental Outlook 2030; it depicts the global trend in biodiversity over time.

The effects of land use on biodiversity can be illustrated by considering habitat conversion, fragmentation, and degradation in several regional studies, and we have selected well-documented studies to illustrate the general process. It is important to consider regional changes in land cover because the factors that drive land use and link it to land cover are best understood at 'subglobal' levels (Kummer and Turner, 1994). The following sections examine (1) the complex ways that biophysical and socioeconomic factors affect land use, (2) the linkage between land use and habitat conversion, fragmentation, and degradation, and (3) the effects of land use on biodiversity.

Habitat Conversion

Deforestation in Southeast Asia

The tropical rain forests of Southeast Asia have declined dramatically since the end of World War II (in the late 1940s). Before humans arrived, the Philippines, Indonesia, Malaysia, Vietnam, and Thailand were completely forested (see Figure 3). Their rich dipterocarp forests were heavily logged (primarily for export) after the war ended. The Philippines currently retains less than 26% of its original forest cover; Malaysia retains more forest, but it is being extensively harvested (Figure 12). The rates of deforestation in the Philippines are well documented and staggering (Collins *et al.*, 1991; Kummer, 1992). From 1948 to 1987, 55% of the forest was lost. From 1969 to 1988, the rate of deforestation was more than 2% per year – or 2 ha every 5 min! The latest FRA2010 reports for the year 2010 – 22% of the total land area in East Asia as being forest, 35% for South and Southeast Asia, 35%

Figure 11 Historical trends in global biodiversity. Reproduced from OECD (2008).

Figure 12 Land cover in the 1990s in Southeast Asia. The tropical rain forests that once covered the area have been now reduced to patches in an agricultural landscape. (Reproduced from National Geographic Society (1992) *The National Geographic Atlas of the World*. Washington, DC: National Geographic Society.)

for Europe, 33% for North and Central America and 49% for South America, and 23% for Africa.

The process of habitat loss (deforestation) in the Philippines serves as a model for all of Southeast Asia (Kummer and Turner, 1994). Two linked land uses, logging and subsistence agriculture, are responsible for converting land cover from tropical rain forest to arable land. Logging dipterocarps converted the primary rain forest to a simpler secondary forest. The resulting partial clearing and road construction allowed poor, landless people to remove the secondary forest and expand agriculture.

This two-step process illustrates how human density, global markets, and local socioeconomic conditions work together to cause changes in land cover. Despite the Philippines' extremely dense (303 people per km² in 2010) and still growing population (2.5% in 1993 and 1.8% in 2010), deforestation is not directly driven by the local population. Rather, a global demand for wood, coupled with corrupt and unrestricted logging, cleared land and made it accessible to people in need

of agricultural space. A surplus of landless people was needed to drive the forest conversion to agricultural land, but without logging to open a new frontier, urbanization might have increased and agriculture might have remained more centralized and intense rather than dispersed as it is now.

Southeast Asia in general and the Philippines in particular, has tremendous biodiversity. Diversity in the Philippines is poorly known, but there are >12,000 plants and fungi and >950 terrestrial vertebrates. This incredible diversity is primarily found in a large number (>59) of scattered and poorly protected national parks. Less than 1.3% of the Philippines is managed for conservation, and much of this area is still logged and settled by landless agriculturalists.

The combination of high biodiversity, high endemism, and extreme habitat conversion results in extreme risks of extinction. The magnitude of threat to birds and mammals in Southeast Asia is particularly well known (IUCN (International Union for the Conservation of Nature), 1996). Worldwide, Indonesia has the largest number of birds (104)

and mammals (128) threatened with extinction. The Philippines leads the world in the percentage of its avifauna that is threatened with extinction (15%). These countries are second only to Madagascar in the percentage of mammals threatened with extinction (32%). Vietnam, Thailand, and Malaysia are all in the world's top 20 countries for species endangerment.

To summarize, deforestation in Southeast Asia is an example of how our land use for amenity (dipterocarp logging) and subsistence (agriculture) resources changes land cover and affects biodiversity. Habitat conversion threatens biodiversity, but the greed (exotic wood) and need (agriculture) of a growing global human population fuel the conversion.

Urbanization in Western Washington State

An expanding population and the world's appetite for resources have transformed much of North America from extensive forest and grassland to agricultural and urban land (compare Figures 2 and 3). The general story is similar to the case in Southeast Asia. However, in the Pacific Northwest a more dramatic and permanent conversion of land is occurring at a rapid rate. Logging during the last 50 years has converted more than two-thirds of the primary forest in Washington to secondary forest. Rather than continuing to manage these forests for timber production, much of the land is now being converted to human settlements. In western Washington, for example, human populations have doubled in the last 50 years and are expected to double again in the next 50 years. From 1998 to 2000, Washington is expecting a net gain of one person every 5 min! This places a premium value on land for settlement. The predictable result is a rapid conversion of forest to urban and suburban settlements. Indeed, from 1970 to 1997, Washington lost 2.3 million acres of managed forestland. Urban expansion was responsible for about half of this loss. Rights-of-way and agriculture accounted for the rest.

The increasing urbanization in western Washington threatens to reduce biodiversity. Water flows altered by settlement have reduced the spawning and rearing habitat for the region's spectacular salmon diversity. As a result, several salmon runs have been extinguished and many are now listed as endangered. Loss of forests and intensification of resource extraction and recreation on remaining forests have contributed to the endangerment of several birds (e.g., Spotted Owls, *Strix occidentalis*, and Marbled Murrelets, *Brachyramphus marmoratus*), mammals (e.g., Grizzly Bear, *Ursus arctos*, and Gray Wolf, *Canis lupus*), and amphibians (Larch Mountain Salamander, *Plethodon larselli*). Drainage of wetlands and settlement of native woodlands and grasslands have endangered amphibians (Oregon Spotted Frog, *Rana luteiventris*), insects (Oregon Silverspot butterfly, *Speyeria zerene*), mammals (Western Gray Squirrel, *Sciurus griseus*), and reptiles (Western Pond Turtle, *Clemmys marmorata*).

Some species benefit whenever land cover changes. A good example of such a species is the American Crow (*Corvus brachyrhynchos*) in western Washington. Crows are found only in close association with human settlement. As a result, their numbers have increased 10-fold from 1960 to 1995. Increases in human commensals like crows may have a ripple effect through the native biota. Crows prey on the eggs and young of other birds, which may limit their reproduction and reduce

overall biodiversity close to human settlements even in remaining forest reserves.

Habitat Fragmentation

The loss of native habitat as lands are converted for human use splinters the remaining habitat into small fragments afloat in a human-dominated matrix. Such "habitat fragmentation" is most evident on a global scale when we compare the original and current distributions of forests (Figure 13). Contiguous primary forests have been removed to varying degrees, resulting in a patchwork of forest islands in a sea of settlement, agriculture, and second growth forests.

Forest fragmentation affects biodiversity by (1) outright loss of habitat (recall Southeast Asia), (2) creation of forest edges that differ from interior forest in many physical and biological properties (e.g., wind speed, humidity, temperature, and predator populations), and (3) disruption of movement and dispersal patterns of forest species. The effects of habitat fragmentation depend on the type of land cover that surrounds the fragments (the "matrix"). In general, when the matrix is similar to the native habitat (e.g., secondary forest surrounding native forest), the effects of fragmentation are less than when the matrix is dominated by human settlements or agriculture. The size of the remaining fragment is also important; large fragments conserve more biodiversity than small ones (Figure 14).

A variety of recent studies of fragmentation in the tropics suggest that habitat fragmentation reduces global biodiversity but not necessarily local biodiversity (Schelhas and Greenberg, 1996; Laurance and Bierregaard, 1997). This seeming paradox occurs because some species benefit whereas others suffer from fragmentation. The result is that local communities change composition after fragmentation, but the overall number of species in a local area does not necessarily decline. Forest interior specialists and wide-ranging species, notably predators, may go extinct with extensive fragmentation, thus lowering global biodiversity. Generalist and exotic species typically increase in fragmented habitats. Research suggests that many forest species tolerate considerable fragmentation because they can utilize the surrounding matrix. The extent of their ability to sustain viable populations depends on resources being available in the matrix and similarity of the matrix to the remaining native habitat.

Research in Singapore and Hong Kong is beginning to reveal the long-term effects of fragmentation. Forest fragments on these islands have been isolated for 150–350 years. Extinction of birds and mammals has been severe, but many plants are able to persist. Forest interior plants that are sensitive to changes in temperature and humidity (such as orchids and epiphytes) are also extinguished by fragmentation.

Habitat Degradation

Changes in land use can affect biodiversity without changing land cover. Land cover can remain essentially the same whereas the intensity of use increases and degrades habitat. Three forms of land use that degrade land cover rather than drastically changing it are (1) agricultural intensification, (2)

Figure 13 Fragmentation of the world's forests at present (b) compared to in preagricultural time (a). About half of the forest that was present under modern (i.e., post-Pleistocene) climatic conditions, and before the spread of human influence, has disappeared largely through the impact of man's activities. The spread of agriculture and animal husbandry, the harvesting of forests for timber and fuel, and the expansion of populated areas have all taken their toll on forests. The causes and timing of forest loss differ between regions and forest types, as do the current trends in change in forest cover. Until 1995, WCMC's work focused on tropical moist forests because of their high species diversity. GIS data were first assembled for closed moist tropical forests and used to publish the three volumes of the Conservation Atlas of Tropical Forests, covering Asia (1991), Africa (1992), and the Americas (1996). Because digital data were rare at this time, the process of assembling the forest cover data sets involved digitizing manually many paper maps. Continuing on from the tropical moist forest mapping, the next major initiative was to create the first 'World Forest Map'. This was produced in 1996 and was the first digital global forest map showing actual forest extent and protected areas with forested land. Since this achievement, significant work has been carried out to improve data sources and fill in gaps which occurred in this first attempt. This led to the production of the 'Global Overview of Forest Conservation CDROM' in 1997.

recreation, and (3) forest management for sustainable timber production.

Agricultural Intensification in Europe

Agriculture is the dominant form of land use in Europe. Conversion of forests to agricultural lands has resulted in dramatic changes in land cover. Forests once covered more than 80% of Europe, but today they cover 45% of the land (FRA2010). In contrast, slightly more than 40% of the

European landmass is now agricultural. Over one-third of this land is permanent grassland maintained for grazing; the remainder is arable land. Conversion of forest to agriculture is no longer a major conservation concern in portions of Europe like Britain that have few remaining primary forests. Instead, the intensification of agricultural practices is degrading the conservation value of lands with grave consequences for biodiversity.

Agricultural intensification in Europe comes in many guises (Newton, 1998). (1) Increased use of chemical pesticides

Figure 14 Preagricultural land cover as modeled by the BIOME model (Prentice *et al.*, 1992) and current land cover as modeled by the IMAGE 2.4 model (Bouwman *et al.*, 2006).

and fertilizers. (2) Removal of hedges to increase field size. (3) Plowing in late summer after harvest rather than waiting until the following spring. (4) Draining wetlands to increase arable and pasture lands. (5) Conversion of mixed farms that produced a variety of animal and plant products to monoculture cereal farms. (6) Earlier harvest dates. (7) Intensive grassland management to increase grass growth. (8) Increased stocking density of sheep in hill country.

These changes in agricultural practices cause declines in bird distribution and density for three main reasons (Newton, 1998): (1) chemicals and early harvests reduce breeding success and survivorship of birds; (2) breeding and foraging habitat is reduced by hedge removal, land

drainage, late summer plowing, intensive grassland management, and increased grazing; and (3) habitat diversity and resulting bird community diversity are reduced when mixed farms are converted to monocultures. The results of these changes have been dramatic. It is suspected that intensification has affected 42% of bird species of conservation concern in Europe. Nearly 90% of the 26 farmland birds in Britain decreased their range of occurrence from 1970 to 1990, and those species using pastures were negatively affected by increasing grazing intensity. Specific aspects of agricultural intensification affect particular species, but on the whole this form of habitat degradation threatens a significant portion of the common, as well as the rare, European avifauna.

Influence of Recreation on Wildlife Communities

As our landscape becomes more dominated by urban and agricultural land, our psychological need to visit and explore the last remaining wild places increases. We often fulfill this desire by camping, hiking, nature watching, hunting, and fishing in wildlands. These seemingly benign activities can affect biodiversity by harassing animals, trampling plants, and altering competitive, facilitative, and predator–prey relationships (Knight and Gutzwiller, 1995). Although recreation in wildlands rarely changes land cover, its effects are often greatest near settlements, thereby extending the actual area modified by settlement.

How campers and fishermen affect salmon-scavenging birds in the Pacific Northwest of North America is a good example of the subtle ways that our land use affects biodiversity without changing land cover. Three species of birds (American Crow, Common Raven (*Corvus corax*), and Bald Eagle (*Haliaeetus leucocephalus*)) vie for salmon that die after spawning each fall and winter. Bald Eagles are the largest and dominant scavenger, but they are also the least tolerant of human activity. Sport fishermen float and wade rivers in search of live salmon and often flush eagles from their meals. This disrupts eagle foraging and may lead to lower overwinter survival and reduced population viability. The rarity of eagles and their status as a national icon increase the desire of nature watchers to observe them during the winter, thereby disturbing them even further. Recreation effects do not stop here. Camping areas along rivers are common and they provide consistent sources of food that fuel an increase in the wildland crow abundance and distribution. Crows are tolerant of humans and quickly return to carcasses after disturbance. They attempt to eat carcasses dominated by eagles and ravens but rarely succeed until humans displace the eagles (and often ravens), thereby incidentally allowing crows to eat without the check of competitors.

Effects of Intensive Timber Management

Timber harvest directly affects biodiversity by (1) facilitating land cover change through clearing land for agriculture and settlement and (2) fragmenting contiguous primary reserves (*see* Habitat Conversion) discussed earlier. Intensive forest management to produce timber may also affect biodiversity in more subtle ways by (1) reducing the average age of the forest, (2) simplifying the age structure and diversity within forest stands, and (3) increasing the frequency of disturbance in forests.

An intensively managed forest is like an intensively managed agricultural field, with the focus on producing the most marketable timber in the least amount of time. However, the effects of timber management on biodiversity appear to be much less than the effects of agricultural intensification. Animals with large space requirements, especially requirements for the interiors of mature forests, do not fare well in managed forests. But animals and plants that utilize clearings, thickets, and young forests thrive in managed forests, which can actually increase local biodiversity by providing habitat for such species. Nonetheless, the loss of sensitive interior forest species usually leads to lower global biodiversity.

The long-term effects of intensive timber management on biodiversity are poorly known. We do not know if managed forests provide adequate resources for many birds during the nonbreeding season, nor do we know how the shifting nature

of forest patches in time and space, so typical of managed forests, affects the ability of plants and animals to maintain viable populations connected by dispersal. It is safe to conclude that maintaining forested land cover is an important contribution to global conservation. The maintenance of managed forests, that perpetuate native forest trees and some of the biodiversity dependent on them certainly helps stem the global loss of native habitat to agriculture and settlement.

Methodological Issues in the Estimation of Land Cover and Land Use

Much of the information presented in this article depends on the estimation of current land use and land cover on a global scale. Our conclusions depend directly on the quality of these estimates. Therefore it is important for the reader to have some insights into how these data are obtained and the degree of uncertainty they contain.

How Are Land Cover and Land Use Estimated?

Land cover is estimated directly by aerial photography at small scales and by satellite imagery at large scales. Aerial photographs resolve fine details in land cover at local or regional scales. Satellite imagery detects features over hundreds of kilometers, but small details are missed because the resolution is coarser.

An important satellite used for imaging the earth is Landsat. Its imaging abilities have improved over the years: Current Landsat TM (thematic mapper) images have better resolution (30 m × 30 m) that permits the fine-scaled discrimination of land covers. Another satellite that is widely used is the Advanced Very High Resolution Radiometer (AVHRR). Its wider swath and coarser resolution (1.1 km) are good for describing large areas of vegetation.

Although modern land cover can be estimated directly using photography and satellite imagery, land use cannot always be derived from the images. Hence statistics of land use supplement or substitute for imagery. The Food and Agriculture Organization of the United Nations (FAO) has reported tabulated data on land use and cover on an annual basis since the 1950s (these data are used in Figure 6). The FAO does not gather data independently but rather compiles national data from returned questionnaires. Globally, the FAO is an important source for time-series estimates of land use and cover from the second half of the twentieth century till present. Recent advances in global satellite products resulted in the GlobCover project. It is an ESA initiative which began in 2005 in partnership with JRC, EEA, FAO, UNEP, GOFC-GOLD, and IGBP. The GlobCover project has developed a service capable of delivering global composites and land cover maps using as input observations from the 300 m MERIS sensor on board the ENVISAT satellite mission ([see http://ionia1.esrin.esa.int/](http://ionia1.esrin.esa.int/)).

Limitations in Estimating Land Cover and Land Use

Virtually every determination of land use and land cover is an estimate that includes some level of smoothing, averaging, and guessing. The general conclusions we make about how land use

affects land cover and biodiversity are not affected by these limitations. However, the application of the maps and processes to specific areas on the planet may fail because of estimation.

An important limitation occurs in large-scale mapping of land use and cover. Some minimum mapping unit (the resolution) is used in all compilations of land cover and use. Only one use or cover can be assigned to this minimum unit, and it is the dominant use or cover that is assigned and assumed to occur uniformly over the entire unit. For example, a unit that is simply recorded as forest might actually be covered by 40% forest, 30% lake, 20% grassland, and 10% building. Recording only the dominant cover reduces the occurrence of dispersed (rarely dominant) covers that typify many human-dominated land covers. Therefore, large-scale maps likely underestimate the actual effect that humans have on land cover.

Projected early estimates of land use and cover are by necessity approximations. The map of preagricultural land cover (see Figure 3) was derived entirely by modeling the plant growth suspected under varying climatological and soil conditions. Cropland estimates in the 1700s were estimated by assuming that 0.2 ha of land was cleared for each human (Richards, 1990). This number is highly debatable because it varies considerably per region and per time period (Klein Goldewijk *et al.*, 2011). Even the population size at that time was an estimate and has considerable uncertainty in many regions (Klein Goldewijk *et al.*, 2010). Regional estimates of land cover and use are also of inconsistent quality. FAO data vary greatly in quality by country because uniform scales and cover categories are not used. Yet even these large sources of estimation and inaccuracy do not affect the general conclusion that at global scale agriculture has increased tremendously, replaced native forests and grasslands, and caused declines in biodiversity.

Another important bias is an underestimation of habitat degradation. Mapping and imagery capture the basic pattern of habitat conversion and fragmentation, but rarely detect changes in the quality of habitats that retain their basic structure. Selective logging, understory trampling and removal, and disturbance by human presence are not recorded on global scales. Regional, local, and more subjective measures are needed to assess these changes in land use.

Glossary

Cap and trade A type of “market-based incentive” that sets a regulatory requirement that firms or other entities covered under the program achieve an aggregate environmental target (such as a maximum amount of pollution or minimum quantity of habitat preservation), and allows the compliance obligation to be traded across firms to meet the objective at lowest cost.

Certification Procedure of determining whether a particular process is conducted in an ecologically benign fashion (also referred to as ecolabeling).

Command and control Policy instrument in which regulated firms must meet individual environmental targets, often requiring the use of specific technologies. Command and control policies contrast with “market-based incentives,” which allow firms more flexibility in how to meet aggregate environmental targets.

Conservation concession Type of “payment for ecosystem services” arrangement in which a buyer

purchases the right to manage a large tract of natural habitat for conservation purposes instead of commercial exploitation.

Individual transferable quota (ITQ) Type of “market-based incentive” in which regulators set an aggregate limit on harvests of an open access resource (typically fish), assign “property rights” for the allowable catch to individual participants, and permit participants to trade those property rights.

Market economy Organization of economic activity in which private individuals buy and sell goods at prices that balance supply and demand.

Market-based incentives Policy designed to change behavior by altering the price paid, or cost borne, by a person engaged in an activity that affects biodiversity.

Payments for ecosystem services (PES) A type of “market-based incentive” that compensates communities, individuals, or other entities whose actions increase the supply of “public goods” from natural ecosystems.

Introduction

The topic, “Market Economy and Biodiversity,” could be interpreted in several ways.

This article focuses on three interpretations and their consequences:

1. A “market economy” might be defined as a *laissez faire*, private ownership system for the production and distribution of goods. A private market economy tends to underprovide public goods. Because biodiversity gives rise to public goods, such a system will not preserve as much biodiversity as would be socially desirable.
2. The above observation notwithstanding, some of the benefits of biodiversity use can be privately appropriated. We could then think in terms of markets for certain aspects of biodiversity that might be embodied in private goods. A popular strategy for biodiversity protection in recent decades has been to capitalize on these privately appropriable values by encouraging markets in sustainably produced goods and services. The authors review some considerations in the development of such markets.
3. Although there are “missing markets” for the public goods provided by biodiversity, public action such as regulation can create artificial markets for some of these goods. Creating markets for biodiversity services can move a market economy closer to the ideal of an efficient,

perfectly competitive economy, in which all goods are priced to reflect their value to society. The authors consider some examples and limitations of such markets.

Biodiversity in a Private Ownership Market Economy

In a private, unregulated market economy, private agents guided by self-interest decide for themselves what to make, buy, and consume. A celebrated result dating back to Adam Smith's *Wealth of Nations* (1904 (1776)) holds that the “invisible hand” of the market will generate a socially desirable outcome even though it is driven by the selfish interests of myriad independent actors. This result was later formalized in what is known in economics as the “First Welfare Theorem”: A perfectly competitive market economy is efficient. (Efficiency has a specific and limited meaning in economics: An outcome is efficient if no one can be made better off without making another worse off.) Efficiency does not address another social objective: equity. However, another fundamental result, known as the Second Welfare Theorem, holds that any efficient outcome – including any that are both efficient and equitable – can be achieved by first reallocating the initial distribution of wealth and then allowing trading in a market economy. There is, however, controversy as to whether it is ever possible to reallocate wealth without altering the

incentives to amass wealth, which would violate the assumptions under which the welfare theorems are derived.

Even introductory economics courses quickly teach their students that the perfectly competitive market economy as envisioned by Smith and mathematically formalized in the middle of the twentieth century by Nobel laureates such as Kenneth Arrow, Gerard Debreu, and John Nash rests on a number of very restrictive assumptions. For readers interested in environmental policy, the most problematic of these assumptions is that there are complete markets; that is, all goods in the economy are, in fact, owned by someone, and, consequently, if one person could realize greater satisfaction from a good than could its current owner, the former will purchase the good from the latter. This sounds like a reasonable depiction of the circumstances of ownership of, say, bread, cars, and cell phones. For what types of goods is this description not adequate?

The answer, in brief, is “public goods.” It may be best to define a public good by contrasting it with a private good. You and I cannot both consume all of the same loaf of bread, because bread is a private good. It is by definition, a good from whose enjoyment I can exclude you – if I have a loaf of bread, I can prevent you from simply taking it from me without compensating me a mutually agreed-on amount (Of course in most societies, preventing you from appropriating my belongings involves more than personal defense; police and courts play a role as well. Such mechanisms are no less necessary in the allocation of public goods than they are in the defense of private ones, but the authors will abstract from further consideration of them here.) – and whose enjoyment is rival – if I eat my loaf of bread, you cannot eat the same loaf of bread. A public good such as environmental quality, in contrast, is neither excludable nor rival. You cannot be excluded from enjoying the benefits of, say, cleaner air, even if it is my actions that have resulted in the air being cleaner. Nor does my consumption of clean air diminish in any way the benefits you enjoy from cleaner air.

Biodiversity gives rise to many public goods. For example, preserved natural ecosystems may both harbor a diverse collection of species and provide downstream communities with protection against flooding by retaining water. The flood protection, however, is necessarily available to all members of the downstream communities if it is available to any. There are numerous other examples. Consider, for instance, the simple moral or esthetic satisfaction one realizes from knowing that such unique and fascinating creatures as giant pandas, California condors, and tigers continue to exist. This is a quintessential public good. My satisfaction in knowing that there are still tigers in the wild in no way reduces the satisfaction you may take in the same knowledge. Furthermore, villagers in India may “pay for” preserving tigers in that tigers they refrain from killing may attack their livestock or themselves. These villagers are providing a benefit to people elsewhere who care about the continued existence of tigers for purely moral or esthetic reasons.

The types of markets envisioned by Smith are incapable of allocating public goods efficiently. The reason is simple. Goods are efficiently produced when the benefits accruing to all members of society collectively from one additional unit of their production are exactly offset by the cost of that

production. This balancing occurs naturally when a private purchaser compares the benefit she alone receives from the purchase of a good with price she must pay for it, and that price is exactly the same as the incremental cost the good’s provider incurs to offer.

When one provides a public good, however, the benefits accrue to many people. Unless one accounts for the benefits to others when making the choice of whether to provide a public good, the public good will be undersupplied. This would not occur if everyone who benefited could be compelled to pay for the benefits she receives, but this is where the problems of nonexcludability and nonrivalry arise. People will not choose voluntarily to pay their fair share of the cost of providing public goods because each would be better off to let others pay their shares and to “free ride” on the benefits the others provide.

Consider again the tiger example. Those of us in the wealthier countries who care about the survival of tigers could pay villagers not to kill the tigers, or perhaps pay to relocate the villagers to areas away from tigers. If I were willing to pay for this outcome, though, why would you want to “buy” a good that I was providing to you anyway? Perhaps we could devise a system under which we both contributed to the payments necessary to compensate Indian villagers for tiger preservation. When you consider that such a scheme would have to involve millions of people to cover all the beneficiaries of tiger preservation, however, you appreciate that what we are then contemplating is really a public program for the provision of a public good – an alternative to a private free market.

The organization of economic activity into more-or-less private markets is, by and large, a phenomenon that began several hundred years ago in the West and has expanded worldwide in more recent decades (while the world’s major economies have increasingly been organized along market lines, virtually all remain “mixed” economies, in which economic activity is apportioned in varying degrees between private and public sectors). (For an interesting perspective on changes in social views concerning private self-interest over the centuries, see [Heilbroner, 1999](#).) During this period over which market economies became predominant, the pace of population and economic growth was historically unprecedented. When Columbus arrived in the New World fewer than half a billion people inhabited the planet. Population did not increase to a billion until the early years of the nineteenth century. It took more than a century to reach two billion, but then rose to 3 billion by 1960, and doubled again between then and the end of the millennium ([De Long, 1998](#)). Even as the numbers of people on the planet skyrocketed, their economic activity increased still more rapidly. J Bradford DeLong estimates the level of income at which the vast majority of the world’s population barely subsisted in 1500 as 115 current US dollars per capita. That figure increased steadily to \$210 in 1800, \$679 in 1900, \$1622 in 1950, and something greater than \$6500 today. Multiplying population and per capita income figures, the scale of economic activity increased by a factor of 1000 in the course of the last 500 years.

The scale of economic activity neither tracks exactly the degradation of the environment in general nor the decline in

biodiversity. Technological improvements may result in the production of both more valuable and less environmentally damaging goods. The empirical fact is, however, that biodiversity has declined with the appearance and expansion of modern market economies. It is easy to link the causes of biodiversity loss with the hallmarks of economic growth. Overharvesting results when growing demands for fish, timber, and other biological resources interact with emerging technologies for their extraction and exploitation. Modern market economies are not conducive to the types of social norms and local institutions that have, in many cases, led to sustainable resource extraction from common-pool resources in small-scale preindustrial communities (e.g., [Ostrom, 1990](#)). International trade and travel are leading causes of the introduction of exotic diseases, pests, and predators that have eliminated native populations, particularly in isolated habitats. (It is worth noting, however, that prehistoric human migrations also had devastating effects on native biota. Paleontological evidence suggests that the extinction of American megafauna were at least suspiciously contemporary with the migration of humans across the Bering land bridge, even if experts disagree as to the culpability of humans. The extinction of Pacific island fauna, such as the giant Moa of New Zealand, has been more definitively linked to the arrival of Polynesian voyagers and, in some instances more importantly, the rats and pigs they brought with them.) In the early nineteenth century, William Blake wrote that the industrial revolution had brought “dark satanic mills,” to “England’s green and pleasant land,” and by the end of the twentieth century the industrial air and water pollution that had transformed landscapes in the worlds’ wealthier nations was also to be found, often in greater quantities and concentrations, in less-developed countries. Perhaps most importantly, the sheer scale of human activity has resulted in the destruction of natural habitats to provide more area for industry, residences, and agriculture.

While it is accurate to say that the world’s most prosperous economies are now those that follow a more-or-less “market” paradigm, blame for ecological damage may not be laid exclusively at the doorstep of market economies. The Soviet Union wreaked incredible havoc on its native ecosystems ([Feshbach and Friendly, 1993](#)). Other economies with legacies of central planning have also often shown disregard for environmental degradation (see, e.g., [World Bank and the State Environmental Protection Agency of China \(World Bank\), 2007](#), on China; or [Kirby, 2004](#), on North Korea). (It is somewhat ironic that states whose governments purport to represent the interests of their citizenry as a whole have sometimes had abysmal records in providing for the common welfare through environmental protection. We argue that public action is needed to provide public goods, but it has often been the case that the economies whose public sectors were most dominant provided the least of the public good of environmental protection.)

One could argue whether the emergence of market economies and their associated technologies and mores itself drove the decline of biodiversity, or if other more fundamental factors drove both; consider for example, [Max Weber’s celebrated treatise on *The Protestant Ethic and the Spirit of Capitalism* \(1958 \(1904–1905\)\)](#). [Diamond \(1999\)](#) advances the fascinating

thesis that the distribution of biodiversity underlay the global dominance that Western Europe eventually achieved: Western Europeans – and their far-flung progeny – came to control much of the world because they were endowed with the richest biodiversity to exploit. If this is true, one might say that biodiversity sowed the seeds of its own destruction through a circuitous process encompassing ever more productive agriculture, the domestication of animals, coevolution with pathogens, the emergence of larger and larger polities, accelerating technological progress, and the breakneck rate of growth the authors have summarized above.

Whether or not the emergence of the market economy may be blamed in whole or in part for the biodiversity crisis, there is increasing interest in harnessing markets to halt biodiversity loss. The ways in which this might be done comprise the topic of the remainder of this article. Let us make one more observation before turning to that topic, however. It is commonly observed in the economic literature that environmental improvement is a normal good – that people manifest a greater concern for environmental protection when their incomes increase (see, e.g., [Kolstad, 2000](#)). There may yet be some hope, then, that even if the emergence of market economies is to blame for the decline of biodiversity, the wealth such economies have produced may also be channeled into preserving what is left of the natural world.

Private Markets for Biodiversity-Related Services

The private market economy will not efficiently provide public goods, such as those associated with biodiversity. Not all of the services associated with biodiversity are public goods, however. Consider, for example, experiences associated with travel and tourism. In some nature reserves, admission is restricted and entrance fees are charged. If it is, in fact, feasible to exclude those who do not pay for a good from enjoying it, the good is essentially rendered private and it may be effectively preserved in a private market economy.

In other cases, it may not be feasible to restrict entry *per se*, but if tourists visiting an area require overnight accommodation, guides, or specialized forms of transport, it may be possible to restrict access to these and charge a price for, say, hotel rooms, that includes some compensation for the unique biodiversity to which guests have access.

Such “ecotourism” ventures are examples of a broader strategy of making sustainable use of biodiversity. A sustainable use strategy was advocated in policy statements of major conservation groups in the 1980s and 1990s ([IUCN et al., 1981, 1991](#)) and has since often been a major item in international conservation policy and, more to the point, international conservation and development strategy. The development component has been particularly important, as there is a rough inverse correlation between the economic performance and the biodiversity endowments of nations, with the greatest diversity of species often found in the some of the least prosperous regions.

It was then hoped that by making sustainable use of biodiversity, incentives would be created for its conservation. Besides ecotourism, these sustainable use strategies include collection and sale of products from natural areas (often

classified in forest areas as “nontimber forest products”), “bioprospecting” (the search among naturally occurring biological products for chemical entities of value in agricultural, industrial, and, particularly, pharmaceutical applications), and sustainable hunting, farming, and timber harvesting.

There can be little dispute that consumer willingness-to-pay for the sustainable exploitation of natural products creates incentives for the maintenance of the sources of such products. What has proved to be considerably more controversial, however, is whether promotion of such markets is in fact a viable and desirable conservation strategy. Some interrelated issues arise in the consideration of that question:

- Do such markets provide sufficient incentives for conservation?
- Do such markets provide incentives for the conservation of biodiversity *per se*, or rather for selected components of biodiversity, with adverse consequences for others?
- Is the promotion of markets for natural products a cost-effective conservation strategy, or would limited conservation resources be better devoted to other approaches?

These questions have been addressed in a lively debate on the efficacy of Integrated Conservation and Development Projects (ICDPs), ventures intended to achieve the twin goals of biodiversity conservation and economic development by promoting the sustainable use of natural systems. While ICDPs received considerable attention and funding in the 1990s, they have attracted criticism from both conservation practitioners (Terborgh, 1999; Oates, 1999; Terborgh *et al.*, 2002) and social science commentators (Wells *et al.*, 1992, 1999; Southgate, 1998; Ferarro and Simpson, 2002), who suggest that confusion between conservation and development objectives sometimes results in neither being met.

Let us briefly consider the questions posed above in turn. The answer to the first must certainly be “no;” the global community cares about biodiversity for a suite of both instrumental and intangible reasons. Since the demand for particular products does not reflect less tangible concerns for the existence of other life forms, such a demand will never result in the appropriate level of conservation. While this argument is easily demonstrated (see, e.g., Pearce and Moran, 1994), it does not necessarily imply that sustainable use is not a useful strategy to conservation in a world willing to devote only limited resources to conservation. While one might argue that sustainable use strategies do not motivate enough conservation, they may have the virtue of motivating at least some conservation.

Expectations may need to be tempered, however. A fundamental result in economics holds that economic value increases with scarcity. In economic parlance, a payment that arises solely as compensation for parting with a scarce good is known as a rent (or sometimes more explicitly as a “scarcity rent”). Put in another way, a rent is a payment over and above the cost of providing a good. (Economic nomenclature can become somewhat balky. If one is a stickler for exactitude, she might insist instead that an economic rent be defined as the opportunity cost of selling a scarce good to one prospective purchaser rather than to another). While society’s concern for the decline of biodiversity arises from the growing

appreciation that the benefits of nature are growing increasingly scarce *vis a vis* the scale of the artificial world, it does not necessarily follow that all of the goods and services to which nature might give rise – and especially those that might be appropriated in private markets – are growing desperately scarce. One must be careful to distinguish between compensation paid for tangible investments and the rents commanded by access to nature *per se*. One might, for example, build a luxury hotel in the midst of stunning natural beauty, but much of the price of a night’s stay there may reflect compensation for investment in the hotel rather than payment for access to the surrounding nature. There remain many, many very attractive places in the world in which to construct hotels, and very few of them are sufficiently unique as to command extremely high rents to benefit their indigenous settings.

Similar arguments have been made concerning the value of biodiversity for use in new product development. Bioprospecting agreements, which have typically involved pharmaceutical and agricultural biotechnology firms, allow companies access to undeveloped habitat that could harbor organisms with genetic information useful for developing new products in exchange for monetary compensation to host communities or countries. There was considerable enthusiasm in 1991 when Merck, one of the world’s largest pharmaceutical companies, and Costa Rica’s National Biodiversity Institute entered into the first international biodiversity contract. A number of other companies and ventures followed. While it is true that nature has provided a vast collection of blueprints for new product development, many advocates have been disappointed by the lack of success to date in bioprospecting. There have been no spectacular discoveries for which developing countries have been compensated, and many of the pioneering bioprospecting ventures have lapsed or been abandoned over time (MacIlwain, 1998; Eisner, 2003; Firn, 2003). While it is not yet clear what the ultimate commercial success of bioprospecting will be, neither its commercial nor ecological goals have yet been reached. (Of course, the lack of resulting commercial products would not necessarily be unexpected, even if prospects were generally favorable. The pharmaceutical research industry is notoriously risky, and for any single project, failure is far more likely than success.)

Some authors have argued that this record arises not because biodiversity does not afford frequent enough sources of new products, but, paradoxically, because potential sources of new products are too abundant. The value of an untested species as a lead in the development of a new product is not determined by simply multiplying the value of the product being sought times the probability that the species under consideration will lead to its discovery. Rather, the value of the untested species is the value of the product being sought times the probability that the species under consideration will lead to its discovery times the probability that the new product will not be discovered among any other available natural or artificial sources (Simpson *et al.*, 1996; see also Rausser and Small, 2000; Costello and Ward, 2006). If nature or synthetic chemistry can provide a multitude of alternatives, bioprospectors will not be willing to pay much for any particular natural lead.

There are, of course, any number of other reasons for which natural sites that could be used for tourism or bioprospecting should be preserved; and, in fact, the development of new products may confer substantial benefits over and above those that may be appropriated by private developers (Craft and Simpson, 2001). These observations underscore our main point; however, markets for the privately appropriable benefits of biodiversity may serve only to preserve a small fraction of the resources about which society cares.

Let us now turn to the second question, which concerns the character of the conservation motivated by sustainable use strategies. Commercial ventures in ecotourism or nontimber forest products are often focused on a subset of attributes or products of an area, and the focus on one element of a system may come at the cost of another. It is sometimes alleged that ecotourism ventures may “love nature to death” by allowing overexploitation and excessive use (see, e.g., Honey, 1999). (The authors consider in this discussion whether, in focusing on one set of assets, ecoentrepreneurs hasten the degradation of another. A related issue is whether, in a rush to exploit natural assets, ecoentrepreneurs hasten the degradation of the very assets on which their enterprises depend. The authors will consider this second issue below in their discussion of property rights.) In some instances, biodiversity-rich areas may attract tourists not so much for their biological as for their topographical wonders – waterfalls such as Angel and Victoria Falls come to mind – and tourism promoters might see elements of biodiversity such as poisonous animals or large predators as impediments to tourist access rather than enhancements to the overall experience (Terborgh, 1999).

Similar phenomena arise in the collection of nontimber forest products. Harvesting edible products from the wild necessarily means that nutrients are removed from the ecosystem that would otherwise have been available to indigenous animals (Peters, 1994). Moreover, the history of agriculture is essentially a record of increased concentration and specialization. Those plants that humans found more attractive were selected and cultivated, while those that competed with crops for space, sunlight, and nutrients were selectively eliminated. Ironically, conservation initiatives intended to promote the collection of “natural products” have, on occasion, led to the establishment of *de facto* plantations of things such as tagua nut trees (Chomitz and Kumari, 1996). Similar phenomena may be encountered in situations in which the preservation of some “desirable” animals may mean the culling of those that prey on or compete with them.

Whether one regards such “managed natural systems” as viable conservation approaches may depend on one’s objectives and sense of possibilities. To some biologists such as John Terborgh (1999), the conservation of biodiversity means the preservation of systems large enough to admit the continuation of natural processes of evolution, including predation by large and dangerous animals. Others would be satisfied by the adoption of agricultural production processes that are simply less intensive than the more industrial alternatives now available (see, e.g., Daily and Ellison, 2002).

Sustainable alternatives to conventional products have gained an additional foothold in the marketplace through the

certification of “green” products. Many people are reluctant to buy things such as lumber, ivory, fish, or coffee without some assurance that they have not caused undue environmental harm. By certifying such products, organizations such as Green Seal or the Forest Stewardship Council enhance their value to environmentally conscious consumers. Such labeling programs help lower the information-gathering costs of determining product-specific biodiversity impacts for consumers who are willing to pay a premium for goods and services produced in a more sustainable way.

However, the potential of certification programs is limited by the public good characteristics of biodiversity conservation already mentioned: Each consumer who pays more for a product or service than it would cost to purchase an alternative, less ecofriendly item is, in effect, making a contribution for conservation. Other consumers, even though they may have similar environmental sentiments, will be tempted to free-ride on such contributions. (See Sedjo and Swallow (2002) or Mason (2006) for formal analyses of some of these issues.)

Advocacy of a sustainable use approach begs a question. If sustainable use is, in fact, sustainable – i.e., if it both conduces to the survival of the biological assets on which it depends and provides a livelihood for the people conducting it – why would international conservation donors need to underwrite it? Why would the local people who stand to profit from the exploitation of their biodiversity not decide to do so without the assistance of foreign donors (Simpson and Sedjo, 1996)?

Several answers might be proposed. First and least satisfactorily, one might suppose that local people do not know what is best for them. As this strains credulity and smacks of condescension, let us proceed to a second potential explanation: Local people may face constraints in technology transfer or capital investment that prevent them from exploiting otherwise profitable opportunities. There may well be merit to this argument, and a cogent model of such constraints and their implications for conservation policy has been proposed (Groom and Palmer, 2010). It should, however, be noted that such arguments may cut both ways. Constraints on capital and credit could prevent local people from investing in ecotourism hotels or bioprospecting laboratories, but such constraints might also prevent them from acquiring chainsaws or building hydroelectric dams (see Rowthorn and Brown (1999) for a formal model of the sometimes counterintuitive effects of lower interest rates on conservation). (One of the authors has heard a revealing, if possibly apocryphal, tale of a nontimber forest product collection ICDP in Madagascar that proved so successful in enhancing local incomes that villagers were able to purchase chainsaws.)

A third possibility is that sustainable exploitation of natural products would generally not be profitable absent subsidies from conservation donors. This possibility seems the most parsimonious explanation of the two facts that, first, sustainable use projects often do not rise indigenously, and second, that foreign donations for sustainable use projects are often made in the form of grants rather than loans.

If, then, subsidies are required to motivate the establishment of markets, the next question to ask is whether such subsidies are the most cost-effective way in which to achieve conservation objectives. Ferraro and Simpson (2002) present a

simple model arguing that they are not. Heuristically, if conservation donors care about conservation, they can generate more effect for each conservation dollar by paying for conservation directly rather than by paying for the purchase of assets (ecotourism facilities, bioprospecting laboratories, and investment in human capital) that only indirectly advance the conservation objective. It should be noted, however, that this result arises from a highly schematic representation of the economic incentives facing both local people and conservation donors, and makes no allowance for political and social factors that could be very important in real-world conservation decisions. Other authors have suggested a richer range of possibilities (see, e.g., [Groom and Palmer, 2010](#)), and it may not be surprising that recent research indicates that World Bank-funded development projects that incorporated biodiversity conservation goals were no less successful, but were less costly, than development-only projects ([Kareiva et al., 2008](#)).

Creating New Markets for Biodiversity Services Using Public Policy

The innovations to engage the private sector in conservation just discussed focused on preserving biodiversity as a joint output used in the production of other goods and services, and were not always effective tools in stemming species loss. While these initiatives can work in certain circumstances, their limited successes suggests that mechanisms to harness conservation financing should target as directly as possible the desired outcomes – either preservation of specific species or habitat more generally.

Integrating market economics and biodiversity conservation provides other promising approaches to achieve this objective. As a result, enthusiasm for involving the private sector in conservation activities has shifted rather than waned. In recent decades, market-based policies have been adopted to address a variety of environmental and conservation priorities, with cap-and-trade programs such as the US Acid Rain Program for sulfur dioxide and the E.U. Emissions Trading System for greenhouse gases offering two widely known examples.

Market-based approaches like cap-and-trade programs create a regulatory requirement that firms or other entities covered under the program not exceed an aggregate environmental target (such as the amount of pollution emitted) and then allow the compliance obligation to be traded across emitters to meet the objective at lowest cost. While principles of market economics are used to design such systems, public policies (and possibly public financing) are needed to give them force. The approach can be applied to biodiversity conservation by setting a species- or habitat-based target, such as maximum quantity of fish harvested or minimum forested area preserved. Market-based mechanisms for conservation include not only quantity-based instruments (which rely on caps or quotas), but also price-based instruments such as pollution taxes or conservation subsidies.

Fishery management is one of the most prominent examples in which regulatory institutions have created market mechanisms to address species loss resulting from the “tragedy of the commons” ([Hardin, 1968](#)) under which open access to

a common pool resource results in its overexploitation. “Catch share” systems create a maximum allowable harvesting limit and then assign harvesting rights to a limited number of participants.

Recall that the fundamental problem with protecting biodiversity in a market economy is that no one owns all of the attributes of biodiversity. Thus, it is impossible to structure transactions in which payments are made from one party to another to preserve biodiversity. This problem would, of course, be obviated if ownership rights could be assigned in the attributes of biodiversity. The most prevalent approach to fishery privatization is the Individual Transferable Quota (ITQ), a system in which a regulator sets a total allowable catch and allocates tradable catch shares to private owners in the market – essentially a cap-and-trade program for fisheries. ITQs and other catch share programs started to gain traction in the 1980s after decades of overharvesting and ineffective policy approaches led to severe declines in commercially valuable fish stocks. Prior to catch share systems, many countries sought to reverse fishery collapse via command-and-control policies restricting fishery inputs such as season length, number of vessels, and technology. Such approaches often had the unintended consequence of spurring a “race to fish” in which actual harvests were not limited, while fishers competed ever more aggressively for a dwindling supply. Based on the trajectory of overharvesting seen in the twentieth century, a widely cited study predicted global fishery collapse by 2048 ([Worm et al., 2006](#)).

In contrast to command-and-control policies, ITQs employ a market-based approach in which regulators create and allocate property rights to fish harvests and allow those rights to be traded. Overall catch limits are set by regulators with input from ecologists, and programs can cover single or multiple species. Secure property rights give fishers an incentive to harvest sustainably, instead of out-competing other vessels to catch as much as possible before stocks disappear. Other similar systems include territorial use rights programs (essentially marine concession areas), which can be coupled with catch limits, and co-operatives, which allocate property rights to groups rather than individuals. The success of any particular catch share mechanism depends on ecological and socioeconomic factors. However, a firm, enforceable catch limit set at a sustainable level is an element critical to success that is common across these different mechanisms. Unfortunately, ecological advice is not always heeded in setting limits, as demonstrated by one study of the EU over 1987–2006, which found that policy-makers routinely exceeded scientific recommendations when setting catch limits, often by large margins ([Piet et al., 2010](#)).

ITQs represented more than 10% of ocean fish harvests as of 2008 ([Chu, 2008](#)). [EDF \(2010\)](#) has documented 275 catch share programs, of which 80% use tradable shares to create a fully market-based system (most nontradable catch share programs allocate rights to co-operatives or traditional groups). In total, such programs cover more than 500 fish species in 35 countries ([EDF, 2010](#)). ITQs and other catch share mechanisms remain concentrated in New Zealand, Australia, Iceland, Canada, and the US, but they have begun to gain traction in South America, Africa, and Asia more recently.

Using fishery regulation to create market-based incentives for conservation has had promising results to date. [Costello](#)

et al. (2008) found that commercial fisheries managed under ITQs were only half as likely to collapse as those without ITQs, based on fishery landings data from 1950 to 2003. Fishers under ITQs experience higher profits as a result of rebounding harvests and lower harvesting costs.

The Alaskan halibut and sablefish ITQ program provides an example of these successes (Bonzon *et al.*, 2010). In the 1980s, the Alaskan halibut fishery had fallen prey to an extreme “race for fish” situation in which overcapitalization of the vessel fleet led regulators to restrict the season to only a few days annually. The frenzy of activity during this curtailed season prompted concerns about worker safety conditions and inability to provide the market with fresh fish throughout the year, while catch limits were still exceeded. Since an ITQ system was introduced in 1995 (later expanded to include sablefish), profits have increased due to lower costs and a longer season that allows for more fresh fish sales. In addition, worker safety has improved, sablefish bycatch has decreased, and stocks are not overfished. The US National Marine Fishery Service sets the total catch limit annually and also coordinates with the even more comprehensive Integrated Groundfish ITQ across the border in British Columbia.

While catch share programs have arisen in recent decades in the context of commercial fisheries hard hit by over-exploitation, they echo similar mechanisms that evolved among traditional societies. In fact, some contemporary catch share programs are the direct descendants of such systems, including customary fishery rights mechanisms in Papua New Guinea, Fiji, the Solomon Islands, and Vanuatu, as well as fishing co-operatives in Japan (Bonzon *et al.*, 2010). Although the property rights conferred by these traditional systems are not always tradable, they embody a core principle of market economics by effectively privatizing an open-access resource.

Fishery catch shares demonstrate how a market-based regulatory program can protect biodiversity in the case of a commercial product where the buyer side of the market – seafood consumers – is well established. However, as already noted, biodiversity provides not only commercially salable products, but also many other services of value to society for which there is no obvious buyer, including a suite of ecosystem services such as flood protection and maintenance of a robust genetic library. Moreover, these ecosystem services are the products of complex biological systems, whereas ITQs and related approaches typically focus on a few commercially salient elements of diverse systems. Market-based mechanisms can also be designed to capture and market the benefits of broader systems in order to finance biodiversity preservation, however. In the past decade, the paradigm of payments for ecosystem services (PES) has arisen in part to address this issue.

PES is an umbrella term that can apply to any number of arrangements between buyers of conservation services and sellers able to provide these services or to manage land to generate them. Such programs include tradable permits, conservation easements, direct land purchases, and other approaches. Nongovernmental organizations (NGOs) are frequently involved, providing technical, institutional, or financial support. The buyers who participate in PES programs can include governments themselves, or they can be private firms fulfilling a regulatory requirement to offset destructive

activities or voluntarily opting in to display corporate social responsibility. Because the types of ecosystem services targeted by most PES initiatives are pure public goods such as flood protection and carbon sequestration, the potential for strictly voluntary contributions to support PES at a large scale seems unlikely, however. Government funding or regulatory requirements for industry participation are probably needed to realize the full potential of these programs.

PES offers a flexible but direct approach to conservation, allowing buyers to seek out biodiversity services where they can be provided at least cost. As already noted, direct payments for land uses that foster ecosystem services – and to an even greater extent, performance-based biodiversity payments – hold out promise to reach conservation targets more efficiently than previous mechanisms. As Ferraro and Kiss (2002) put it, “The basic principle is that the cheapest way to get something you want is to pay for what you want (e.g., protected rain forest), rather than pay for something indirectly related to it (e.g., capital for improving ecotourism).”

Several governments have spearheaded PES programs financed by public (or in some cases, international) funds. Wunder *et al.* (2008) documented eight government-financed PES programs from China to Europe to Latin America. Most of these programs transfer subsidy payments to farmers or other individual landowners in exchange for undertaking specific land use or agricultural practices that generate a variety of ecosystem services. The US Conservation Reserve Program, established in 1985, is the longest-running such scheme. It pays farmers to retire land in order to reduce soil erosion, improve water quality, harbor wildlife, and, more recently, sequester carbon. Mexico’s Payment for Hydrological Environmental Services program, started in 2003, is similar in concept but focuses on preservation of forested areas for watershed and aquifer protection (though carbon sequestration cobenefits are also anticipated).

A still more recent class of initiatives that have attempted to link conservation sellers with private sector buyers includes conservation concessions. Conservation concessions have emerged in the past decade as a much-touted incentive-based biodiversity conservation tool primarily reliant on international financing. Essentially a hybrid of a conservation easement and a commercial concession, the mechanism allows investors (which to date have predominantly been international NGOs) to finance conservation by compensating would-be users for the gains they would have realized by exploiting their resources. Conservation International (CI) pioneered the idea, helping to establish initial projects in Peru (2001) and Guyana (2002). Since then, similar programs have been proposed or established in Mexico, Cameroon, Sierra Leone, Bolivia, Indonesia, and elsewhere by CI and other NGOs.

Conservation concessions and similar agreements offer an approach for conserving large tracts of publicly or communally owned land where host countries or communities are reluctant to establish new protected areas without compensation. Thus, their scale and supporting institutional arrangements are distinct from PES schemes that target individual landholders who control relatively small areas. Like easements, concessions restrict land uses, effectively transferring use rights without a transfer of land ownership. In theory, they

provide a mechanism for conservation to compete directly with timber, fishing, mining, and other extractive interests for access to desirable land, though in practice, they have been largely used as a preventive strategy to protect pristine habitats that have not yet come under direct extractive pressures.

While they offer the potential for large-scale habitat preservation at low transaction costs, results remain modest when compared to the extent of resource extraction in commercial concessions (Pearce, 2004). For instance, timber concessions in Central Africa frequently extend to millions of hectares (Karsenty, 2007), while conservation concessions are typically approximately or less than 100,000 ha each. However, the size of concessions does compare favorably with the land area conserved under national PES programs; Costa Rica's PES program had enrolled 270,000 ha of forest as of 2005, while Mexico's had targeted 600,000 ha by 2006 (Wunder *et al.*, 2008). A recent survey finds that momentum for biodiversity markets has been sustained despite the recent downturn in economic activity more generally (Madsen *et al.*, 2011).

Concessions can vary substantially in their implementation. Programs can permit different land uses, with some barring commercial activities and others allowing sustainable harvesting, ecotourism, and research. They might involve payments to local residents, community associations, regional or national governments, or some combination of these groups. They can also target diverse biomes from grasslands to temperate forests to aquatic habitats, though most projects are located in tropical forests. This diversity makes concessions potentially relevant in a wide variety of future applications and provides flexibility to be adapted if significant public or mandatory financing becomes available to supplement the voluntary private efforts that have supported concessions to date.

Proponents of market-based biodiversity conservation efforts typically tout their effectiveness and low costs relative to other policy approaches, but another advantage seen in both the government-financed PES and privately financed conservation concession examples is that tracts of undeveloped land can provide many ecosystem services besides harboring biodiversity. Marketing these "bundled" services could offer a means to leverage multiple sources of funding to preserve highly valued sites. Tropical forests in particular have the potential to supply carbon sequestration and hydrological regulation, both classified as regulating services by the Millennium Ecosystem Assessment, in tandem with biodiversity protection. Combining biodiversity preservation with provisioning or cultural services, like sustainable harvesting or ecotourism activities, might also be feasible. For example, some participants in Chile's area-based catch share program for abalone and other benthic organisms have combined fish harvesting with dive tourism (Bonzon *et al.*, 2010). However, the latter approach risks degrading pristine sites, making these activities incompatible with environmental goals (Terborgh, 1999).

Bundling biodiversity conservation with carbon sequestration offers particular promise as a means to access additional funding for conservation with the growing interest in REDD (Reducing Emissions from Deforestation and Forest Degradation in Developing Countries), which is being discussed under the United Nations Framework Convention on Climate Change (UNFCCC) (see OECD, 2008). This synergy

would allow biodiversity conservation to take advantage of new markets created to address other externalities – in this case, climate change from greenhouse gas emissions. If REDD is adopted as a climate mitigation strategy under a post-Kyoto climate agreement, large sums of money could become available for reducing deforestation and degradation (e.g., Kindermann *et al.*, 2008).

Challenges to Creating Markets for Biodiversity

Tradable quota systems, conservation concessions, and other market mechanisms reduce costs relative to command-and-control regulation by creating incentives for those entities with the lowest costs of achieving biodiversity benefits to take the actual physical measures required to reduce environmental impact. Despite these advantages, market-based biodiversity conservation approaches are not invulnerable to criticism. The authors discuss three broad challenges associated with setting up such programs (though they are not all unique to market mechanisms and could also apply to traditional conservation approaches). These include implementation issues; equity and development considerations; and the high costs of conservation relative to the benefits – or at least, those benefits likely to be reflected in market mechanisms.

Applying market-based mechanisms to preserve biodiversity raises a number of nontrivial implementation challenges. In particular, biodiversity-rich habitat and associated ecosystem services are extremely heterogeneous; preserving land in a temperate forest gives rise to very different ecosystem services than a similarly sized tract in a tropical forest, and even within the same biome, habitat can vary substantially in the number and type of species supported. Although habitat area is a convenient metric, delineating tradable units in terms of area alone ignores these quality differences – a particular problem if poor quality habitat also costs the least to preserve. This issue has been recognized in the environmental economics literature for many years; the possibility that high-abatement-cost polluters might be concentrated in "hotspots" may necessitate further restrictions on trade in such areas or the imposition of different trading ratios depending on the location at which pollution is emitted (Tietenberg, 1985). Even in the case of catch share programs where compliance is measured in terms of species-specific harvest limits, complementary policies like marine reserves could be warranted to protect particularly sensitive aquatic habitats such as spawning grounds.

According to Peterson *et al.* (2008), "the more specifically ecosystems are categorized to match ecology, the more barriers to trade these ecological differences erect" (see also Chomitz *et al.*, 2004). A program in which local developers can trade obligations to maintain habitat for a particular endangered species might afford only limited cost savings if there is little flexibility in the choice of feasible habitat configurations. The cost of conserving a certain area of habitat, or even of sheltering a certain number of species, might be greatly reduced if we relaxed any requirements regarding the character of the habitat or the identity of the species. Alternatively, costs will likely be higher if restrictions are placed on trades to preserve particular locales or populations.

Besides the complications related to measuring and trading units of highly heterogeneous biodiversity services, market-based programs for habitat conservation also raise concerns about additionality, leakage, permanence, and verification – four different issues that must be addressed to achieve real, long-term conservation gains relative to business-as-usual conditions (Wunder, 2007). Additionality relates to projects targeting land that would likely remain undeveloped even without the conservation program; in such a situation, the program has yielded no “additional” environmental gains. Many projects have focused on remote, sparsely settled areas to date because of limited funds and reluctance to displace land uses contributing to economic development (Barnes *et al.*, 2006). Because the opportunity cost of land is equal to the net present value of the stream of future earnings it is expected to generate, land that is likely to remain undeveloped well into the future has a low net present value, making it less costly to preserve – but also less threatened. Projects targeting these areas divert resources away from sites where they might have more of an impact. Market-based programs can be designed with selection criteria that reflect the likelihood of land conversion to increase additionality.

Even if conservation initiatives successfully preserve natural ecosystems on sites that would likely be converted to other uses, leakage – the displacement of extractive activities to other undeveloped land – can weaken aggregate conservation outcomes (Chomitz, 2002; Wunder, 2007; ICMM, 2005). It would do little good to secure the preservation of one tract of pristine ecosystem if, by doing so, development pressure were simply diverted to the next-most-advantageously located tract of pristine ecosystem.

Preventing leakage (also sometimes called “slippage”) is particularly difficult when considering habitats that produce commodities such as timber and minerals that are exchanged in international trade. Any reduction in supply from the market could induce an increase in the price the product commands in international trade, which will, in turn, attract more supply from other sources. The elasticity of demand for harvested products is an important determinant of leakage; less leakage will occur when demand is elastic, while more is expected when demand is relatively inelastic. Fortunately, empirical evidence to date suggests that hectare-for-hectare leakage is unlikely (though biodiversity loss could still be high without complete leakage if activities are displaced from less- to more-diverse land). For example, an empirical study of the Conservation Reserve Program in the US found that for every 100 acres of land enrolled in the program, 20 acres of non-cropland was converted to agricultural production (Wu, 2000).

Permanence is another critical feature of conservation programs that might be in conflict with a market-based approach. The very flexibility of market-based conservation programs could become a drawback if such programs simply delay species extinction for one or two decades because land is eventually converted. Setting firm aggregate conservation targets and structuring contracts to apply long-term and allow the option to be renewed can help address this issue.

Monitoring and verification are also key implementation issues, given the remoteness of many conservation activities

and the difficulty in measuring them. Aggregate conservation targets will have little meaning if land use practices and species survival outcomes cannot be credibly assessed. Technologies such as satellite-based monitoring can be helpful for verification in remote areas, and programs can be structured to provide payments only after certain commitments have been fulfilled by the sellers of conservation services.

Equity and development concerns present a different set of challenges from applying market-based approaches to biodiversity conservation. As is true in transactions for pure private goods, market signals lead to the most efficient outcome – the greatest overall monetary benefit at the lowest cost, given the preexisting distribution of resources. But such outcomes may not ensure the well-being of the worst-off members of society or foster a level playing field. For instance, fishery ITQs have confronted whether to auction off rights to the highest bidder, freely allocate them to fishers based on historical harvests, or distribute them using some other approach. This initial distribution of property rights has large implications for who reaps the benefits and bears the costs of the program, even though it does not affect the total monetary benefits and costs to society of instituting a catch share system.

In cases where conservation projects help local people establish secure property rights (whether to fish harvests, land, or other valuable resources), they can facilitate economic gains for host communities while improving environmental outcomes by shifting land or oceans away from an open access regime. For instance, devolving control over wildlife habitat to local communities encouraged economic development through sustainable resource management and ecotourism in Zimbabwe’s CAMPFIRE program (Frost and Bond, 2008). Similarly, control over use rights to tracts of Guatemala’s Maya Biosphere Reserve has allowed local communities to reap gains through sustainable forest management (Avery and Southgate, 2002).

When property rights are unaffected by PES or other market mechanisms, economic benefits experienced by communities are not expected to be appreciably different under conservation than other resource uses if payments cover but do not exceed true opportunity costs. Indeed, community welfare could even decrease if outsiders pursue property rights to key resources in anticipation of payments.

Even if the communities directly involved benefit, conservation projects could have regressive outcomes by taking land out of production and raising the costs of commodities on which the poor spend disproportionately more of their incomes. If conservation induces substantial land use changes, some of the changes in the prices of agricultural products, wages, and other affected commodities that result could exacerbate inequality (Zilberman *et al.*, 2008; Ross *et al.*, forthcoming).

Recent surges in global food prices in response to higher fuel prices, biofuel production, and demand from expanding economies suggest that potential food and resource price effects of large-scale conservation programs should be scrutinized. Food prices are expected to remain high over the coming decade (von Braun *et al.*, 2008). Food security is, of course, an absolutely vital concern of many people in developing countries. This is particularly true of those who barely sustain themselves at the margins of imperiled ecosystems. Conversely, fishery catch shares that increase the amount of biological resources available for direct human use through more

sustainable management could have beneficial effects on food availability. The general conclusion to be drawn from these examples is that conservation programs on a large enough scale – regardless of the mechanisms – are likely to affect the production and consumption of other goods, triggering a variety of positive or negative impacts on individuals within a market economy.

Even when market-based programs identify equitable and relatively low-cost approaches to conserve biodiversity, their costs can still be high – perhaps too high to achieve desired conservation outcomes. Once institutions and property rights have been established, biodiversity conservation enters the market economy as another service, and individuals must perceive the private benefits they will reap from supplying it to outweigh the opportunity costs.

Undeveloped lands are often arrayed in a haphazard patchwork, and the cost of their conservation can be high, as many areas are now accessible to transportation and services that make them more attractive for development. While the costs of acquiring and managing threatened habitat in some areas of the developing world have been estimated to be relative bargains at US \$10 per hectare or less (Pimm *et al.*, 2001), it is these low-opportunity cost areas that raise concerns about additionality. Much land remains in areas that are not yet subject to high development pressure, but studies examining the potential opportunity costs of conservation have shown them to be substantial in many cases. Sandker *et al.* (2007) showed that logging a forest tract and planting oil palm would provide much greater economic benefits to both local communities and potential migrant laborers in Malinau district, Kalimantan, Indonesia over a 40-year timeframe. The authors' simulation results indicated that PES of US \$25–50 million annually would be required to make up the opportunity cost of economic gains derived from timber and oil palm harvests.

Whether the resources are sufficient to pay the costs of conservation will depend, at least in part, on how many of the benefits of conservation have been internalized by the program. Just as consumer products and services like sustainable coffee and ecotourism only reflect a portion of the ecosystem services provided by natural habitats, even market-based conservation programs mandated by governments could be insufficient to motivate sufficient biodiversity preservation if they do not reflect the full suite of services from which people around the globe derive fulfillment. For example, an economic assessment of Madagascar's Masoala National Park found that although conservation would generate greater social benefits globally, the financial returns to logging exceeded those from an ICDP (Kremen *et al.*, 2000). In the case of fishery catch share programs, it is possible at least in theory that it could be rational to drive low-growth fisheries to extinction under private management (Clark *et al.*, 2010). This result would not be socially optimal if the fish species provide other benefits to society besides food consumption.

Conclusion

Market-driven economic growth and biodiversity conservation have long been seen as a fundamental conflict. In recent decades, conservationists have attempted to change this

perception by harnessing private markets to protect biodiversity. This convergence has followed two basic approaches. The first relies on private markets to capture individuals' willingness to pay for those aspects of biodiversity that are reflected in consumer goods and services. The second uses public policy tools to create market-based mechanisms to motivate the conservation of both open access resources and ecosystem services. Both strategies have seen some limited successes to date, and the second approach holds particular promise for conservation efforts that are both large-scale and cost-effective. Market-based approaches do not necessarily resolve all of the dilemmas that have plagued past species conservation efforts, however, from implementing credible programs to covering high costs to achieving equitable outcomes for the local communities affected by conservation. Any conclusions that might now be offered concerning the relationship of "market economy and biodiversity" must remain provisional, awaiting both greater experience with the application of market incentives and greater appreciation of their potential limitations.

Glossary

Ecosystem services Wide array of benefits that ecosystems and their biodiversity confer on humanity.

Marine Broadly defined to include coastal (on land, within a narrow fringe adjacent to saltwater), intertidal, nearshore, and open ocean.

Production function approach An approach that models ecosystem services as the relationship between ecological

and human inputs (e.g., the structure and functions of an ecological system, human labor and capital) and outputs valued by humans.

Valuation Act of estimating or setting the value of something.

Value Relative worth, merit, or importance. Can be measured in various ways, including but not limited to monetary metrics.

Introduction to Marine Ecosystem Services

Humans have always benefited from marine ecosystems, enjoying resources such as seafood and opportunities for activities like recreation and marine transportation. These ecosystems also provide indirect benefits by sequestering carbon and playing key roles in the regulatory processes of other global cycles. Benefits derived from these systems are broadly characterized as the ecosystem services provided by marine ecosystems. As identified by the Millennium Ecosystem Assessment (MA) (2005b), marine ecosystem services span four major categories: provisioning, regulating, cultural, and supporting services (Table 1). Broad assessments of marine and coastal ecosystems services based on the MA can be found in Agardy *et al.* (2005) and the United Nations Environment Program (2006), as well as other synthesis documents (e.g., Peterson and Lubchenco, 1997). Costanza (2000), Patterson and Glavovic (2008), and Wilson and Liu (2008) also provide useful overviews of these services, as do descriptions of the particular services provided by fish populations (e.g., Holmlund and Hammer, 1999), coral reef ecosystems (e.g., Moberg and Folke, 1999) and mangroves (e.g., Ronnback, 1999).

Among the four types of marine ecosystem services, provisioning services such as food from capture fisheries, aquaculture, and wild foods are the most obvious and easily valued. About 80 million tons of fish were landed in marine capture fisheries worldwide in 2009, and fish account for approximately 16% of the annual animal protein consumption by humans (FAO Fisheries Department, 2010). Globally, more than 1.5 billion people rely on fish for almost 20% of their animal protein. On average, each person living in 2009 ate 17.2 kg of fish (including fish from aquaculture; the proportion from capture fisheries alone is difficult to calculate given nonfood uses of wild fish) (FAO Fisheries Department, 2010). Other provisioning services include timber and fiber from mangroves and seagrass beds, and biochemicals for cosmetics and food additives. The potential also exists for developing novel natural products from marine species with medical applications (Carte, 1996). For example, researchers recently found that three marine species collected from offshore oil and gas platforms in California's Santa Barbara Channel had potential for biomedical applications, including

two that inhibit the division of cancer cells grown in the laboratory (Schmitt *et al.*, 2006). In addition, the ocean may become an important energy source: biofuels from algae and power generation from wave and tidal energy have potential for more widespread use. And finally, the world's oceans provide the highways for the global shipping trade.

Marine systems also provide a wide range of regulating services. As vividly highlighted by the human losses wrought by the 2005 hurricanes on the US Gulf Coast, coastal and estuarine wetlands have value for their ability to reduce storm surge elevations and wave heights (Danielsen *et al.*, 2005; Travis, 2005). Other regulating services provided by marine systems include the transformation, detoxification, and sequestration of wastes (Peterson and Lubchenco, 1997). And "blue carbon" – the role oceans can play as carbon sinks – is a service that is gaining interest (Nellemann *et al.*, 2009).

Human societies have always been drawn to the oceans, which have proven to be a rich source of cultural services. In 1995, an estimated 39% of the world's population lived within 100 km of a coast (Burke *et al.*, 2001). In the US, people love to live near the ocean; one study predicts average increases of 3600 people a day moving to coastal counties through 2015 (Culliton, 1998). Coastal tourism is a key component of many economies around the world and is one of the fastest growing and most profitable sectors of tourism (United Nations Environment Program, 2006). Countless intangible benefits are drawn from the oceans, too. For example, many communities define their identities in relation to the coast, people draw inspiration from oceans in numerous ways, and rich ceremonial traditions are intricately linked to the sea.

Finally, the oceans provide essential supporting services that underpin many of the globe's ecological functions. The oceans hold 96.5% of Earth's water (Gleick, 1996) and are a primary driver of the atmosphere's temperature, moisture content, and stability (Colling, 2001). The global cycles of carbon, nitrogen, oxygen, phosphorus, sulfur, and other key elements flow through the oceans (Peterson and Lubchenco, 1997), and marine ecosystems are responsible for approximately 40% of global net primary productivity (Schlesinger, 1991; Melillo *et al.*, 1993). The oceans are home to vast reservoirs of genetic and ecological diversity, arguably the most fundamental source of supporting services as they are directly

Table 1 Ecosystem services provided by marine systems

<i>Types of service</i>	<i>Examples</i>
<i>Provisioning services</i>	
Food production (capture fisheries; aquaculture; and wild foods)	Tuna, crab, lobster; salmon, oysters, shrimp, seaweed; mussels, clams
Fiber production	Mangrove wood, seagrass fiber
Biomass fuel production	Mangrove wood, biofuel from algae
Maintenance of aquatic systems	Shipping, tidal turbines
Generation of genetic resources	Individual salmon stocks, marine diversity for bioprospecting
Production of biochemicals, natural medicines, and pharmaceuticals	Antiviral and anticancer drugs from sponges, carrageenans from seaweed
<i>Regulating services</i>	
Climate regulation	Major role in global CO ₂ cycle
Water regulation	Natural stormwater management by coastal wetlands and floodplains
Erosion regulation	Nearshore vegetation stabilizes shorelines
Water purification and waste treatment	Uptake of nutrients from sewage wastewater, detoxification of PAHs by marine microbes, sequestration of heavy metals
Disease regulation	Natural processes may keep harmful algal blooms and waterborne pathogens in check
Pest regulation	Grazing fish help keep algae from overgrowing coral reefs
Pollination/Assistance of external fertilization	Innumerable marine species require seawater to deliver sperm to egg
Natural hazard regulation	Coastal and estuarine wetlands and coral reefs protect coastlines from storms
<i>Cultural services</i>	
Provision of conditions that support or enhance ethical values (nonuse)	Spiritual fulfillment derived from estuaries, coastlines, and marine waters
Provision of conditions that support or enhance existence values (nonuse)	Belief that all species are worth protecting, no matter their direct value to humans
Provision of recreation and ecotourism opportunities (consumptive and nonconsumptive uses)	Scuba diving, beachcombing, whale watching, boating, snorkeling; fishing, clamming
<i>Supporting services</i>	
Nutrient cycling	Major role in carbon, nitrogen, oxygen, phosphorus, and sulfur cycles
Soil formation	Many salt-marsh surfaces vertically accrete; eelgrass slows water and traps sediment
Primary production	Significant portion of global net primary productivity
Water cycling	Most of Earth's water is in oceans; they are central to the global water cycle

Source: Adapted from Guerry A, Plummer M, Ruckelshaus M, and Harvey C (2011) Ecosystem service assessments for marine conservation. In: Kareiva P, Tallis H, Ricketts T, Daily G, and Polasky S (eds.) *Natural Capital: Theory and Practice of Mapping Ecosystem Services*. Oxford: Oxford University Press.

linked to the rate of evolution and therefore the ability to adapt to a changing climate (Pergams and Kareiva, 2009).

Since the MA, much work has been done in developing and applying new methodologies to model, map, and value ecosystem services (e.g., UNEP and IOC-UNESCO, 2009; Kareiva *et al.*, 2011; UK National Ecosystem Assessment, 2011). A great deal of the original MA was focused on terrestrial systems, but new work—and new political contexts—have sparked the expansion of an ecosystem services framework to marine systems. For example, the UK recently completed a groundbreaking, countrywide assessment of both terrestrial and marine ecosystem services and their value (Stokstad, 2011; UK National Ecosystem Assessment, 2011). Although agricultural production has increased between 1950 and the present, landings of fish and shellfish from UK waters have declined since the 1960s from almost 900,000 t to slightly more than 500,000 t in 2008 (UK National Ecosystem Assessment, 2011). Protection of UK coastlines from storm-induced flooding and erosion has declined in response to a 10% loss of natural habitats such as dunes, kelps, seagrasses

and marshes over the past 60 years (UK National Ecosystem Assessment, 2011).

The MA and subsequent assessments have raised awareness of ecosystem services, the explicit human dependence on them, and the threatened status of many of them. Bringing ecosystem services into the active management of terrestrial and marine ecosystems, however, requires more than just a catalog of services and their total values. More pragmatic is the assessment of the ecological and economic consequences of management activities in particular places. An understanding of how changes in ecosystems are likely to lead to changes in ecosystem services can most clearly provide information to decision makers. Modeling marine ecosystem services can play an important role in providing such insights.

Foundations

Marine ecosystems provide both great opportunities and challenges for the application of the framework of ecosystem

services. The concept of ecosystem services has a long history but has seen a relatively recent resurgence of interest from ecologists, economists, and conservation practitioners. Because ecosystem services are reviewed elsewhere in this volume, we focus here on the conceptual frameworks and methodologies that pertain to marine applications, as well as the challenges facing these applications.

Why Model Marine Ecosystem Services?

Models are important tools for examining the dynamic nature of and interconnections among the biophysical and human elements of marine ecosystems. They provide a way of exploring future scenarios that lie outside the range of past experiences, as well as possible unexpected consequences of policy actions. An ecosystem services framework provides important insights into the challenge of pursuing ecosystem-based management. Ecosystem services are the currencies through which the consequences of ecosystem change flow to people. Using such a framework, ecosystem services and their values can be used as a set of metrics for assessing alternative management interventions and their potential impacts on economic or social well-being.

Models of ecosystems that incorporate both biophysical and human components can present policy makers with an enormous set of potential indicators for gauging the changes brought about by policies. Ecosystem services – the “ecological endpoints” of the system that are directly connected to human well-being (Boyd, 2007) – can provide a guide for winnowing this set down. In the context of ecosystem modeling, such a framework avoids the potential problem of double counting the value of “intermediate” ecological elements (e.g., forage fish) that support other “endpoint” elements with direct value (e.g., fishery harvests) because the value of the intermediate elements are embedded in the value of the endpoints (Boyd and Banzhaf, 2007).

Ecosystem models that focus on ecosystem services also provide the opportunity to overcome problems arising from traditional management in the marine realm, which generally proceeds sector by sector, with distinct bodies making isolated decisions. These single-sector decisions often affect a broad set of ecosystem services, many of which are outside the scope of their authority. As a result, there has been little effort to consider the ways in which single decisions impact the full suite of things people care about and need.

Using an ecosystems services framework can highlight trade-offs among multiple objectives so that decisions to resolve those trade-offs can be made transparently. Increasingly, scientists and managers are pointing to links between diversity, productivity, and resilience attributes of marine systems and their response to human interventions in conserving, harvesting, and regulating marine ecosystem services (Liu *et al.*, 2007a; Levin and Lubchenco, 2008; Murawski *et al.*, 2009; Chan and Ruckelshaus, 2010). Our ability to model and assess trade-offs among objectives of multiple management sectors (e.g., fisheries, wave or wave energy, recreation) and ecosystem services (e.g., value of fishery landings, kilowatt hours of energy generated, revenue from recreational activities) is needed in order to inform more complex cases

of ecosystem-based management that can accommodate a broader suite of actors (Foley *et al.*, 2010).

Pioneering efforts to use the framework of ecosystem services to understand the connections between activities in one sector and their impacts on others are underway in the marine environment. Decision makers at various levels of government from around the globe, including the [Interagency Ocean Policy Task Force \(IOPTF\) \(2010\)](#), the [European Commission \(2010\)](#), and the recently approved UN Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) have recognized that new approaches are needed to ensure the sustainability of benefits people derive from oceans and coasts ([UN General Assembly \(UNGA\), 2010](#)).

Among these parties, there is currently a great deal of emphasis on marine (or “maritime”) spatial planning. This approach to comprehensive management of marine and coastal systems analyzes current and anticipated uses, identifies areas most suitable for particular activities, and provides a process to better determine how oceans are used and protected now and for future generations (Douvere and Ehler, 2009; Ehler and Douvere, 2009). Ecosystem services provide a framework and a common language for this type of planning process, allowing agencies and private interests to articulate their goals transparently using common terms and to better understand how their decisions interact with those of other users and activities.

Connecting Social and Ecological Systems

Several related conceptual frameworks provide the context within which ecosystem service information is critical to understanding feedbacks between humans and ecosystem conditions in marine and other environments. One of the most important is the notion that humans are an integral part of ecosystems, and so ecosystem models should encompass their behavior (Holland *et al.*, 2010). Similarly, the theory of complex adaptive systems encompasses humans as parts of coupled systems and presents humans as participating in the dynamics of the system (Levin, 1998; Levin and Lubchenco, 2008). The production of ecosystem services involves a combination of ecological functions and human actions and values (Figure 1). In the marine environment, for example, marine ecosystems have fish populations that offer opportunities for commercial and recreational harvests, two of the most valuable services derived from these systems. The human action of harvest, however, is what transforms the potential ecological supply into the actual provision of the ecosystem service (Tallis *et al.*, 2011). Human values in the form of the demand for seafood, the valuation of recreation, and the costs of commercial harvest or recreational angling all determine the value of these services.

Building models to account for the humans who interact with or are affected by an ecological system can therefore provide fundamental insights into the provision and value of ecosystem services. Simple economic models can focus on individual decisions to use more or less of a marine resource, for example. An ecological change that makes it harder to harvest fish is likely to produce a lower level of effort that can be modeled in a simple framework of the demand for that

Figure 1 The production of ecosystem services involves a combination of ecological functions and human actions and values. Recreational fishing as an ecosystem service, for example, depends on the healthy functioning of natural systems that support fish populations. The human action of harvest transforms the potential ecological supply into the actual provision of the ecosystem service.

activity. More complicated models involve complex decisions about where and when to fish, which species to fish for, and so forth (e.g., Sanchirico and Wilen, 1999; Wilen *et al.*, 2002). Similarly, human behavior has more latitude to make adjustments over longer periods of time, and so modeling short-run versus long-run behavior of a system can account for such differences (Holland and Brazee, 1996). As they mature, models of marine ecosystem services can include how humans interact with biophysical components of the system and can incorporate realistic mechanisms for changing those interactions based on economic and other incentives. We include some examples of these kinds of truly linked human and biophysical models in the “Production Function Modeling” section.

The coupled social–ecological systems model developed by Ostrom (2009) is one key conceptual framework that includes interactions between biophysical and social systems. Much of the focus of research guided by this conceptual model is to identify relevant attributes for understanding the dynamics of a coupled social–ecological system (e.g., the lobster fishery in Maine and its fishing community) and the effects of different management approaches (e.g., regulation, incentives) on ecological and ecosystem services (e.g., lobster biomass, landings, biodiversity) and social (e.g., efficiency, equity, accountability) outcomes. Under this framework, the features of governance systems (e.g., property rights systems, operational rules), user groups (e.g., social heterogeneity, leadership), and resource units (e.g., economic value, behavior of harvested species) that give rise to different ecological and social outcomes can be quantitatively or qualitatively assessed using

well-developed methodologies (Cudney-Bueno and Basurto, 2009; Ostrom, 2009; Basurto and Coleman, 2010).

The closely related conceptual framework of coupled human and natural systems touches on similar issues but with a stronger focus on understanding mechanisms and feedbacks (Liu *et al.*, 2007a, 2007b). A critical question this framework poses is the positive or negative direction of feedback loops between human and natural components of a system and the strength of those interactions (Liu *et al.*, 2007b). This modeling framework encourages exploration of temporal and spatial as well as organizational couplings, thresholds, and resilience in linked systems. For example, whether couplings between human and natural components of a marine ecosystem are direct and local or indirect and global can be a key feature influencing how humans and ecosystem services respond to signs of change in the ecosystem, and it is an increasingly important feature with the globalization of both human and natural processes.

One modeling approach that incorporates these frameworks is the integrated ecosystem assessment (IEA). An IEA outlines both a decision analytical framework and a process containing the logical steps necessary for managing ecosystems, including explicit identification of objectives and the indicators for tracking progress, a risk analysis describing the state of the indicators, an evaluation of management strategies, and an overall assessment of ecosystem response (Levin *et al.*, 2009). IEAs have a successful history of application in fishery-based ecosystem management (Caddy, 1999; Sainsbury *et al.*, 2000; Smith *et al.*, 2007); they are designed to be iterative, expanding in scope and sophistication as

information develops over time (e.g., Dennison *et al.*, 2007; Tallis *et al.*, 2010; Samhoury *et al.*, 2011).

IEAs are one example of current approaches to the management of marine ecosystems that can use ecosystem services in a modeling framework. An IEA uses quantitative analyses and ecosystem modeling to support management decisions that address a range of social, economic, and natural conditions. Ecosystem services can provide a set of metrics for assessing these conditions, and modeled changes in their levels can then provide decision makers with a way to compare alternative policies.

Challenges in Modeling Marine Ecosystem Services

From a scientific perspective, the modeling of marine ecosystem services is sufficiently different from the task on land to warrant its own treatment. Marine systems provide some special scientific challenges in the endeavor to map, model, and value ecosystem services. Most models for terrestrial systems use a land-use or land-cover data layer as a foundation for the initial assessment of services, as well as a baseline for exploring how land conversion and land-use change alter ecosystem services. Fundamentally, the same approach works for marine environments. Marine systems have habitats that are altered or used with consequences, and different management approaches yield different habitat conditions and different delivery of services.

We cannot readily “see” most benthic habitat types using satellite imagery or other remote sensing technology, so maps of habitat type and condition are harder to come by in marine systems than they are on land. Also, in marine systems, associations between species and habitat patches are more difficult to discern. The lack of basic land-use and land-cover data for marine systems underscores the need for a modeling approach to ecosystem and food-web dynamics that is less tightly coupled to detailed habitat maps than the approach often taken in terrestrial systems (e.g., Kareiva *et al.*, 2011).

A second shift in perspective required when considering marine ecosystem services stems from the ways in which humans interact with marine environments. We do not live in the sea, and thus many of our actions that affect the marine environment are indirect. We can think of many terrestrial habitats without considering the effects of marine systems on them, but the converse is not true. Activities on land (e.g., coastal development; nutrient, sediment, and pathogen inputs to freshwater; increases in impervious surfaces) have profound effects on nearshore marine systems (Carpenter *et al.*, 1998; Mallin *et al.*, 2000; Diaz and Rosenberg, 2008).

Understanding and modeling marine ecosystem services is also made more difficult by the fact that we generally have less direct control or knowledge of human actions. In terrestrial areas, property rights are the norm, and zoning often dictates what and where actions can take place (both on public and private property). Human activities and their results are also more observable on land. In marine areas, human activities are not typically managed explicitly at a fine scale, and many areas are effectively open access. Thus, it is often more critical to incorporate endogenous behavioral models of people into models of ecosystem services.

Finally, modeling ecosystem services is not a substitute for all other ways of assessing marine and other ecosystems. Concerns about biodiversity of marine ecosystems, for example, may be poorly addressed by a pure ecosystem services approach. Some assert that protection and restoration of marine systems will improve both biodiversity and the ability of the oceans to provide ecosystem services; others point out that trade-offs can occur (Balvanera *et al.*, 2006; Worm *et al.*, 2006; Naem *et al.*, 2009; Palumbi *et al.*, 2009; Klein *et al.*, 2010; Brander, 2010). Ecosystem modeling coupled with observations should not ignore this and other approaches to marine conservation, and they should continue to provide needed evidence for the conditions under which biodiversity and ecosystem service provision are positively related and where trade-offs are likely to occur.

Approaches

The modeling of marine ecosystem services can take a variety of approaches. Although not normally considered a “model,” a straightforward accounting of ecosystem services and their values has played an important role in past assessments, and so it is included in this section as one approach. Many models of ecosystem services take a production function approach in which the structure and functions of an ecological system are combined with human actions and capital to produce an output valued by humans (National Research Council, 2005). This approach has been used to analyze a variety of individual ecosystem services, as well to provide the framework for developing suites of models that encompass multiple services. Each of these approaches is presented in the following sections.

Accounting Approaches and Basic Valuation Methods

The simplest approach to assessing ecosystem services for marine and terrestrial systems is a straightforward accounting of those services and their values. This approach is not one that explicitly models the ecological or human systems, but it has been used to assess marine ecosystem services (Beaumont *et al.*, 2007, 2008). Generally, the approach begins by defining a particular geographic location and then identifying the set of ecosystem services flowing from that area. The assessment can then be as simple as compiling local information on each of these services for that region – e.g., using revenues from an area’s fishery harvests as a measure of the economic value of that type of provisioning service.

A more common method that has been used for terrestrial systems is ecosystem-service mapping (Troy and Wilson, 2006). This method differentiates a particular area by land cover, biome, or some other set of ecologically based landscape or seascape type. Drawing from a standard set of ecosystem service categories (e.g., deGroot *et al.*, 2002), each landscape type (e.g., forestland) is then linked to a set of services (e.g., recreation or carbon sequestration) believed to be provided by that type. The quantity of an ecosystem service produced is then assumed to be linearly related to the area of the landscape type.

From these starting points, local economic data, if they exist, can be used to transform the quantity of ecosystem services into economic values. Such data are not commonly available, however, and so the more typical approach to assigning economic value is to use what is known as *benefit transfer*. Benefit transfer is a method for taking economic data on benefits (or values in general) gathered from one site and applying the data to another site. This method is rarely the “first-best” choice for estimating economic values but the costs of gathering primary, site-specific data have made it a common practice for studies of ecosystem service value (e.g., see Rosenberger and Loomis (2001) and National Research Council (2005) for examples of recreational uses of natural sites). Using the assumption of a linear relation between ecosystem service quantities and landscape area, a “unit value” for a particular ecosystem service and landscape type can then be derived by taking an existing study’s estimated value for a particular ecosystem service and dividing by the area of the studied site’s landscape (e.g., recreation or carbon sequestration value per acre of forestland). These unit values can then be used to assess the value of ecosystem services at other sites for multiple services and landscape types if they are present.

This accounting approach was pioneered by Costanza and colleagues (1997), who estimated global values for 17 ecosystem services for 16 biomes. Their effort included five marine and coastal biomes: open ocean, estuaries, seagrass or algae beds, coral reefs, and ocean shelf. These five biomes accounted for almost two-thirds of the estimated annual \$33 trillion value of Earth’s services. Their use of benefit transfer was almost universal; the original data used in the study were gathered in one or more locations and then projected worldwide.

Accounting approaches such as Costanza *et al.* (1997) are simple and play the important role of raising the awareness of the values of traditionally undervalued, nonmarket ecosystem services. They should be used cautiously, however, with important qualifications in mind. First, this approach imposes linearity on the valuation of ecosystem services, which has the potential to produce biased estimates. Human pressures on ecosystems and the services they provide can result in impacts that respond nonlinearly to changes in the scale of the pressure or change discontinuously if a threshold is crossed (Groffman *et al.*, 2006). The valuation of ecosystems services should therefore account for such nonlinearities if the scale under consideration is more than minimal (Barbier *et al.*, 2008; Koch *et al.*, 2009). The human values that apply to ecosystem services can also exhibit nonlinearities as the quantity or quality of the ecosystem service available changes (Bockstael *et al.*, 2000; Toman, 1998). Again, if the scale of a service under consideration is large, projecting a value estimated for a small change has the potential to produce significant bias. And if more than one service is evaluated, the aggregate value of the group of services is likely to be nonlinear with respect to considering more and more services. If estimates of individual ecosystem service values are used in such an exercise, simply adding them together will again produce a biased estimate of the group’s value. These problems grow more and more significant as the scale of the ecosystem service valuation exercise increases. Given that this

approach is often used to produce national or even global estimates (Anielski and Wilson, 2009; Beaumont *et al.*, 2007, 2008; Ingraham and Foster, 2008; Naidoo *et al.*, 2008), the issue of nonlinearities is an important one.

Second, the method requires rigid association of a particular set of ecosystem services to a particular landscape type; thus it does not allow assessment of how policies might change the flow of ecosystem services and affect their values, short of comparing values under wholesale destruction of the landscape type. Relying on landscape type to assign a fixed presence and quantity of services provides little information to evaluate how a policy will change ecosystem service values in any way other than a change in the landscape type. This “all or nothing” approach may make sense for some cases – for example, replacing forest with open agricultural fields – but not for others, as it is highly unlikely that any policy is capable of converting saltwater estuaries into upland forestland.

A third caution stems from the common use of benefit transfer for ecosystem service mapping exercises and other accounting approaches. The broad categories used in these types of exercises facilitate a comprehensive analysis of ecosystem service values for large geographic areas, but they also subject the analysis to a high likelihood of what is called *generalization error* (Plummer, 2009). As an example, consider the problem of estimating the value of providing “recreation” in a “marine area.” *Recreation* covers scores of possible market and nonmarket activities that take place in natural settings, and some may be present in one marine area but not in others. Also, the presence of human-built infrastructure and the accessibility of the marine area are important determinants of the economic value of the recreational activity. Because these factors can vary widely, using estimates of economic value from one site and applying them to another is likely to produce significant errors if the categories of “recreation” and “marine area” are treated at a high level of generalization.

Finally, existing estimates of economic values for ecosystem services are strongly influenced by the methodology employed to make the estimate. As the NRC report on valuing ecosystem services (2005) emphasizes, not all methodologies are equally good. Happily, several valuation approaches are accepted practice by economists, but the interpretation of the resulting values should be informed by the method used.

Revealed Preferences Methods

Standard economic theory is based on the assumption that observable choices made by individuals reveal their expected valuation of a good or activity (but it also allows for some goods with values that are independent of observable behavior) (Slesnick, 1998). The revealed preference approach is a collection of methods for estimating economic values that rely on observable behavior. The most obvious revealed preference method is the use of market data. The production of commercially harvested finfish and shellfish is a leading example of marine ecosystem services with values that can be estimated with market data. Another revealed preference method that uses market data is known as *hedonic analysis* (Palmquist, 1991; Freeman, 1993; Palmquist, 2003); it analyzes goods (e.g., housing) that are sold as a bundle of

characteristics. In some cases, location-specific characteristics may be part of the bundle and include environmental amenities such as air and water quality or proximity to open space. If ecosystem services are a part of these bundled characteristics – for example, shoreline protection provided by nearshore ecological systems – the marginal value of such a service can be estimated with a hedonic analysis.

A final revealed preference method is useful for cultural ecosystem services such as recreation and other environmental experiences that take place outside any formal market. In this approach, the cost of engaging in the activity can be used to derive estimates of its economic value (Clawson, 1959; Knetsch, 1963). Similar to the assumptions for hedonic models, the recreation “good” can be viewed as a bundle of characteristics, some of which are the environmental features important to the recreational experience. If data are available for visits to multiple sites with varying levels of those features, one can then estimate the contribution of a particular feature to the demand for that recreation and from this estimate the feature’s value (Morey, 1981).

Stated Preference Methods

Stated preference methods also can provide legitimate estimates of economic value. These methods rely on survey questions that ask individuals to make a choice, describe a behavior, or state directly what they would be willing to pay for specified changes in nonmarket goods or services. These methods are increasingly used in economic studies of environmental quality because they offer the opportunity to estimate the value for anything that can be presented as a credible and consequential choice. If conducted with attention to the many standards of care for its execution (Mitchell and Carson, 1989), this method can provide useful estimates of ecosystem service values.

Other Valuation Methods

Other methods are less reliable and particularly prone to misuse when estimating ecosystem service values. A prominent example is the replacement-cost or cost-of-treatment approach. For example, the cost of municipal water treatment for drinking water can be reduced by the presence of a wetland because the wetland system filters and removes pollutants (Day *et al.*, 2004). Using the cost of a human-built alternative treatment method is an approach sometimes taken to estimate the “value” of the wetland, but in general this cost does not have any necessary relation to the actual services provided by a particular wetland. On the one hand, the wetland may not actually provide filtration services (e.g., because of the absence of contaminants that need filtering or biophysical features of the wetland that prevent filtering). On the other hand, the wetland might simultaneously provide a number of other services (such as carbon storage, nursery habitat support for fisheries) that are not captured by this form of valuation. As a result, the replacement-cost approach to estimating the value of an ecosystem service must be used with great care.

One final word about valuation: much of the dialogue about ecosystem services focuses on economic valuation. Economic valuation, however, is far from the only way to value ecosystem services. Although many services (e.g., provisioning

services) are relatively straightforward to value in economic terms, others (e.g., cultural services) often defy economic valuation. The comparison of multiple ecosystem services in a single currency (e.g., dollars) is appealing in some contexts but not appropriate or even desirable in others. Cultural ecosystem services – diverse, nonmaterial benefits that people obtain through their interactions with ecosystems, including spiritual inspiration, cultural identity, and recreation – are difficult but not impossible to value. Various methods (e.g., narrative methods, paired comparisons, structured decision making) can be used to elicit the relative weight that people place on these services (Chan *et al.*, in press).

Production Function Modeling

A production function approach is fundamentally process-based. It represents the relationship between inputs (e.g., the density of mangroves) and outputs (e.g., the degree of protection from storms). Production functions have been used extensively in agriculture, manufacturing, and other sectors of the economy. Ecological production functions can be used to explore how changes in ecosystem structure and function lead to changes in the flows of services (National Research Council, 2005).

Unlike the accounting methods previously discussed (*see* Accounting Approaches and Basic Valuation Methods), a production function approach allows for the comparison of alternative courses of action and their effects on ecosystems and services, and it can thus provide more useful information for decision making. With process-based models, analysts can explore how changes in inputs are likely to lead to changes in outputs. If valuation is of interest, then production function approaches can use both market prices and nonmarket valuation methods to estimate economic value and to show how the monetary value or other value currencies are likely to change under different environmental conditions.

The production function approach has been used to model various ecosystem services on land (Ricketts *et al.*, 2004; Kareiva *et al.*, 2011) and in marine systems (Barbier *et al.*, 2008; Holland *et al.*, 2010). In many cases, the approach is used to model a single ecosystem service, which is appropriate when it is functionally somewhat separate from other services and management actions are focused on that service. In other cases, the services have sufficiently strong connections that a multiple service approach is warranted. Both of these choices are explored in the following sections.

Modeling Single Ecosystem Services: Bioeconomic Models of Fisheries

A leading example of the modeling of a single ecosystem services in marine systems is the modeling of fisheries that incorporates both biological and economic components. For some types of fishery management decisions, a narrow focus on the single ecosystem service of food from fisheries is appropriate. It also provides important lessons for ecosystem service modeling because a critical part of its development has been the evolution of the human behavioral portion of the models. For that reason, an extended discussion

of this type of production function approach is provided in this section.

Of all marine ecosystem service modeling, fisheries models are by far the most sophisticated and have the longest history of use in managing marine systems. Bioeconomic models have been used since the early 1950s to explore how the value generated by fisheries is affected by how they are exploited and regulated. Bioeconomic models have evolved over time from simple models focused on equilibrium outcomes associated with static annual harvests and effort levels (e.g., Gordon, 1954; Schaefer, 1957) to more complex dynamic models that explore the implications of the timing, location, and methods of harvests, the linkages between different species, and the impacts of fisheries on other ecosystem services. From the beginning, these models have emphasized the interconnection of the natural and human components of fisheries and the importance of an approach to modeling that treats human activity as an endogenous part of the system.

It was recognized early on that understanding the optimal exploitation of fisheries would generally require a dynamic modeling approach since fisheries are rarely if ever in equilibrium at some desired state. Scott (1955) introduced the concept of *user cost* to illustrate the trade-offs between harvesting fish today and leaving fish in the water to contribute to future growth. Viewing the fish stock as natural capital, Scott showed that optimal exploitation would require the rate of return from the *in situ* fish stock to equal the rate of return from other uses of that capital (i.e., by extracting and selling fish and thereby transforming them into economic capital).

Although the initial focus of bioeconomic models was on aggregate annual effort and harvests, Gordon's (1954) analysis demonstrated that the value generated by the fishery was also dependent on the spatial distribution of fishing. The exploitation of fisheries over space – and particularly the issue of whether to close some areas to fishing to conserve fish stocks, habitat, and biodiversity – became an important focus of bioeconomic modeling in the late 1990s (e.g., Holland and Brazee, 1996; Sanchirico and Wilen, 1999) and remains so (Costello and Polasky, 2008). It is becoming increasingly clear that spatial heterogeneity of marine ecosystems and of fishing costs provide opportunities to increase the value generated by fishing by managing where and when fishing takes place and which harvest methods are employed. These models show that optimal exploitation depends on relative costs over space in conjunction with spatial variation in productivity (e.g., from differences in suitability and productivity of habitat for species and their prey or from metapopulations with source-sink dynamics).

Another important focus of bioeconomic modeling that has become more prevalent over time is the multispecies nature of fisheries. Many multispecies fishery models focus on the implications of technical interactions that make it difficult and costly to control the relative catch of different species that occupy the same habitat. These models provide insights into how economic incentives or regulations on gear or fishing locations can influence catch composition to increase the value and sustainability of fisheries and reduce undesirable bycatch. Trophic linkages between different fish species are

often thought to be important drivers of fishery productivity and stability. However, they have largely been ignored in the assessment of the productivity of fish stocks and when providing management advice (but see Hollowed *et al.*, 2011). This is not surprising: these relationships are typically poorly understood and difficult to quantify.

Nonetheless, there is recognition that understanding and responding to these species interactions can increase value and improve the sustainability of fisheries. Ecosystem models that attempt to depict entire food webs and the impacts of bottom-up forcing (e.g., by climate) and top-down forcing (e.g., predation and fishing) have been developed in recent years; a few such as Atlantis (Fulton *et al.*, 2004a, 2004b) include an endogenous human harvester component to the model. These models offer the possibility of informing a more holistic ecosystem-based approach to managing fisheries and other activities in the marine environment, but their complexity and the lack of data to parameterize them has so far limited their usefulness in providing specific tactical advice for managing individual fisheries. An increasing number of multispecies bioeconomic models focus on small systems of exploited species (see, e.g., the discussion in the section The American Lobster, Atlantic Herring, and Northeast Multispecies Groundfish Fisheries in the Gulf of Maine). For these smaller systems made up of primarily commercial species, there is often more data and research, making it more feasible to parameterize the models accurately enough to quantitatively evaluate multispecies harvest strategies.

Our ability to understand and model fishery systems in the marine environment is hindered by an inability to observe directly the processes that drive outcomes since they occur under the sea and over vast areas. It is often the perturbations caused by human exploitation of the system and the data gathered by fishermen that enable us to develop an understanding of these systems that is sufficient to create empirically based models capable of providing specific insights that can be applied to the management of these systems as we seek sustainable harvest levels. Bioeconometric models, defined by Smith (2008) as structural models that econometrically estimate one or more parameters of the bioeconomic system, have the potential to reveal both ecological and economic parameters of the system simultaneously and to greatly increase our understanding of these systems at relatively low cost (since they exploit data easily collected by fishermen in the course of normal operations).

This field is not new as it includes empirical applications of the Gordon-Schaefer model dating to the 1950s – but until recently was mostly limited to equilibrium models based on aggregate annual catch and effort. These models did not reveal the underlying microecological and economic processes driving the results and required making strong assumptions about system behavior (e.g., that it tends toward equilibria). In recent years, progress has been made in modeling and parameterizing these processes with dynamic models and disaggregated data. This has made it more feasible to model and predict how changes in the underlying ecological system or changes in factors that drive human behavior will change outcomes and the resulting flow of ecosystem services (e.g., Smith *et al.*, 2008).

Efforts to model a single ecosystem service – such as the critical service of food from fisheries – and the ways in which its delivery or value change under different scenarios are of great utility when decisions are being made sector by sector or when a better understanding of a key service sheds light on a previously understudied aspect of a system. But with decision makers increasingly grappling with multisector decisions, modeling of multiple ecosystem services in the same context can allow for more informed decision making.

Modeling Multiple Ecosystem Services and Examining Trade-Offs

Single-sector management that proceeds without the explicit consideration of how single decisions impact the full suite of things people care about and need can lead to misguided assessments of the true costs and benefits to the environment and society of natural resource management options. For example, mangroves are routinely cleared and the resultant open areas used for shrimp aquaculture. A singular focus on aquaculture as an ecosystem service derived from cleared areas often shows a positive bottom line, as the high market price of shrimp provides strong support for this action from a private perspective. Standing mangroves provide other social and ecological benefits that private owners cannot capture, however. More complete accounting using a multiple ecosystem service framework shows that keeping mangroves intact often has higher social benefits once other services such as wood products, support for offshore fisheries, and coastal protection are taken into account (Sathirathai and Barbier, 2001). In other words, a single-sector approach risks ignoring the multitude of connections among components of natural and social systems. These connections are often important for the maintenance of ecosystem health, human well-being, and the sector of interest itself (Millennium Ecosystem Assessment, 2005b).

The explicit recognition of connections between activities and their consequences for multiple ecosystem benefits allows for the exploration of trade-offs and win-wins. Rodríguez *et al.* (2006) review some of the most frequent ecosystem service trade-offs faced by society. In some cases, trade-offs and win-wins can be explored using a common currency (e.g., dollars, Sathirathai and Barbier, 2001), but various metrics can be used (Tallis *et al.*, 2008, 2011; Lester *et al.*, 2010). As one example, the MA explored trade-offs among various categories of ecosystem services (with axes for each service scaled from –1 to 1 to represent positive or negative change from the baseline) for each of four heuristic scenarios (Millennium Ecosystem Assessment, 2005a).

Explorations of multiple ecosystem services and how they are likely to change under various management scenarios has proceeded in two important directions: detailed explorations of particular situations and the development of tools designed to be applicable in various contexts. We focus here on tools. Research teams have taken a number of different approaches to modeling the flow of multiple ecosystem services and examining trade-offs between them. Here we provide a brief introduction to some of the approaches and tools that are most applicable to modeling marine ecosystem services (Table 2).

Modeling the flows of ecosystem services can take many forms. Artificial Intelligence for Ecosystem Services (ARIES;

www.ariesonline.org) offers a range of approaches including probabilistic Bayesian models, machine learning, and pattern recognition to assess the provision, use, and flow of ecosystem services on a landscape. The tool allows users to evaluate and compare alternative policy and land-use scenarios and their impacts on ecosystem services. The initial marine application of ARIES is in Madagascar in partnership with the United Nations Environment Program's (UNEP's) World Conservation Monitoring Center, where a benefits-transfer approach to ecosystem service valuation is being used (Center for Ocean Solutions, 2011).

More process-based ecosystem service modeling approaches also have emerged. The challenges of applying the land-use or land-cover map-based approach used in terrestrial systems, coupled with the strong foundations of marine ecosystem modeling, has made ecosystem modeling central to the ecosystem services framework for marine systems. Foodweb models such as EcoPath with EcoSim (EwE) (Christensen and Walters, 2004) and ecosystem models such as Atlantis (Fulton *et al.*, 2004a, 2004b) have been used to explore fishery management options in an ecosystem context. These models also have the potential to evaluate a more comprehensive suite of human activities and the ways in which they change the delivery of ecosystem services. Using these models, explorations of the potential outcomes of various human actions can lead to the development of management approaches that consider multiple objectives and trade-offs among objectives.

Integrated Valuation of Ecosystem Services and Trade-offs (InVEST; <http://www.naturalcapitalproject.org>) helps decision makers visualize the impacts of potential management activities by modeling and mapping the delivery, distribution, and economic value of terrestrial, freshwater, and marine ecosystem services under alternative scenarios (for more information, see Kareiva *et al.* (2011) and Guerry *et al.* (2012)). InVEST can be used to identify trade-offs and compatibilities between environmental, economic, and social benefits. Applicable at a range of scales—from local to global—InVEST was designed to play a key role in real-world decision-making processes. The first phase of the approach involves working with stakeholders to identify critical management decisions and to develop scenarios that project how the provision of services might change in response to those decisions as well as to changing climate, population, and so on. Using these scenarios and basic biophysical and social data as inputs, InVEST quantifies and maps a broad range of ecosystem services. To facilitate the use of InVEST in real decision-making contexts, a key design feature of InVEST is the relative simplicity of data required and the free availability of models on the web. InVEST outputs provide decision makers with information about costs, benefits, trade-offs, and synergies of alternative management strategies.

InVEST uses a primarily production function approach to assess how environmental change, as a result of future policies and management decisions, affects the delivery of ecosystem services. Terrestrial InVEST models have been applied around the world to inform a variety of land-use decisions (Kareiva *et al.*, 2011). InVEST's marine tools (see Guerry *et al.*, 2012) were initially released in 2011 and are being applied in Canada, the US, and Belize. Marine InVEST includes models

Table 2 Decision support tools for use in marine environments, with particular attention to: marine applications, spatial mapping of ecosystem services, capacity to analyze trade-offs between services, and the level of technical expertise needed to use the tool

<i>Decision support tool/developer</i>	<i>Description</i>	<i>Marine applications</i>	<i>Spatial mapping of ecosystem services</i>	<i>Analysis of ecosystem service trade-offs</i>	<i>Level of technical expertise needed^a</i>
<i>Artificial Intelligence for Ecosystem Services (ARIES)</i>					
Basque Center for Climate Change (BC3); University of Vermont—Gund Institute for Ecological Economics, Conservation International, and Earth Economics	ARIES is a suite of web-accessible applications—including probabilistic Bayesian models, machine learning, and pattern recognition— used to assess the provision, use, and flow of ecosystem services. ARIES maps both the sources of ecosystem services and their users, along with the flows from ecosystems to users.	ARIES has been used to assess subsistence fisheries and coastal storm regulation in Madagascar.	Yes	Yes	2, 3
<i>Atlantis</i>					
Commonwealth Scientific and Industrial Research Organization (CSIRO) Marine and Atmospheric Research	Atlantis is a three-dimensional, spatially explicit model that incorporates biogeochemical dynamics and fishing behavior. Submodels cover food-web relations, hydrographic processes, and fisheries.	Atlantis has been used to evaluate restructuring of Southeastern Australia fishing fleets, the NOAA Integrated Ecosystem Assessment for the California Current, the Marine Stewardship Council Forage Fish Harvest Guidelines, and groundfish fleet impacts on protected marine mammals in the California Current.	No	Yes	3
<i>Coastal Resilience</i>					
The Nature Conservancy, University of Southern Mississippi, and University of California, Santa Barbara	Coastal Resilience is a spatial planning and action approach that integrates appropriate coastal hazard, ecological, and socioeconomic information within a particular geography. The Coastal Resilience approach is to map sea-level rise and other coastal hazards, natural resources, and human communities at risk and display this information via an internet mapping application that is a data viewer, data discovery tool, and a future scenario mapper.	Coastal Resilience has been used for data exploration with the New York State Emergency Management Office and local towns and villages on Long Island and the Connecticut shores.	No	No	2

Cumulative Impacts

National Center for Ecological Analysis and Synthesis (NCEAS), University of California, Santa Barbara, and Stanford University

The Cumulative Impacts model uses spatial data and expert opinion to assess the ecological consequences of 17 types of human activities. By overlaying maps of human activities and ecosystem vulnerabilities, this model produces a cumulative mapping of ecological impacts.

Cumulative Impacts has been used in a coarse global analysis and in the California Current and the northwestern Hawaiian Islands.

InVEST

The Natural Capital Project—Stanford University, World Wildlife Fund, The Nature Conservancy, and the University of Minnesota

InVEST is composed of a number of models for assessing flows of and changes in different ecosystem services including, but not limited to, carbon storage, wave energy, recreation, fishery production, erosion control, habitat quality, water quality, crop pollination, and timber production. InVEST is a toolbox in ArcGIS and runs on both spatial and nonspatial physical, biological, and economic data and information. (An ArcGIS-independent version is forthcoming.)

InVEST has been used for marine applications in Canada (west coast of Vancouver Island) and Belize, and for land–sea connections in Puget Sound, Galveston Bay, and Chesapeake Bay (US). In addition, it is being used in climate adaptation planning and to inform restoration in the Gulf of Mexico and in Monterey Bay (both US).

Marine Map

MarineMap Consortium—University of California, Santa Barbara, The Nature Conservancy, and EcoTrust

MarineMap is a web-based decision support toolkit to support marine spatial planning processes. The toolkit includes a spatial data viewer and design tools that allow users to networks of prospective marine protected areas. The application also allows users to share their proposals with others and evaluate their proposals against goals defined in the course of any planning process.

MarineMap has been used for the California MLPA Initiative and the Oregon Territorial Sea Planning process (US).

Figure 2 Marine InVEST evaluates how alternative scenarios yield changes in the flow of ecosystem services. First, one translates management or climate scenarios into input data. Inputs include spatially explicit biophysical and socioeconomic information. Next, one feeds input maps into models that predict the delivery of services across the seascape. Intermediate effects of management choices and climate on the flow of services can be evaluated in terms of risks to habitats and changes in water quality. Ecosystem service outputs are expressed in biophysical or socioeconomic units. Some examples of processes or activities that link the models include (numbers correspond to circled numbers on arrows): (1) flow rate and the movement of sediment, nutrients, toxic waste and bacteria; (2) filtration, flows of waste; (3) limiting fishing grounds; (4) light attenuation, sedimentation; (5) water purification; (6) food supply (shellfish); (7) beachgoing; (8) spawning, rearing; and (9) wave attenuation. Adapted from Guerry AD, Ruckelshaus MH, Arkema KK, *et al.* (2012) Modeling benefits from nature: using ecosystem services to inform marine spatial planning. *International Journal of Biodiversity Science, Ecosystem Services and Management*. doi: 10.1080/21513732.2011.647835.

for renewable energy, protection from coastal hazards, fisheries, recreation, aquaculture, aesthetic views, and more (Figure 2).

The Multiscale Integrated Models of Ecosystem Services (MIMES) project represents another attempt to build a suite of models that assess the values of ecosystem services to allow managers to understand the dynamics of ecosystem services, how services are linked to human welfare, and how the flow of services might change under various management scenarios in both terrestrial and marine systems (<http://www.uvm.edu/giee/mimes/>). MIMES involves a relatively complex approach, simulating ecosystems and socio-economic systems and the interactions between them. It calculates values of ecosystem services using marginal cost pricing. MIMES is currently being used by the Massachusetts Ocean Partnership to evaluate the trade-offs between different sectors in marine spatial planning (Center for Ocean Solutions, 2011).

Applications of Marine Ecosystem Service Modeling to Decision Making

Decision contexts for managing ecosystem services in the sea are varied, so it is to be expected that a mix of quantitative and qualitative modeling approaches are being developed and applied to support biodiversity and ecosystem service management in marine systems. Information needed to support the methodologies we highlight in the following sections ranges from observations and empirical data to modeled ecosystem and social responses, expert opinion and traditional local knowledge (e.g., *Kliskey et al., 2009*). Typically, the time frames of decisions, local technical capacity, and the nature of information available for each context dictate the approach employed for ecosystem service modeling. We explore four contexts in the following section that display a wide range of the numbers of services modeled, quantitative complexity, and types of decisions being made.

We start where marine modelers and managers are most at home together – with a fisheries-focused example – and then move to efforts to include a number of different types of services.

The American Lobster, Atlantic Herring, and Northeast Multispecies Groundfish Fisheries in the Gulf of Maine

The American lobster, Atlantic herring, and Northeast multispecies groundfish fisheries in the Gulf of Maine provide an excellent example of a system of interlinked fisheries with a value that might be substantially increased by accounting for linkages between them and with the environment. A number of important environmental, ecological, and economic linkages within these fisheries and with the environment were identified as key processes to study and model (Figure 3). This system is the subject of an interdisciplinary research project funded by the National Science Foundation aimed at understanding these linkages through empirical research and modeling to provide insights into how the management of each fishery and the system as a whole can be improved. The strategy of this research effort is to link and build on the single-species models that are already used for providing management advice by modeling key linkages between the fisheries and with the environment that might be exploited to increase value and sustainability.

The primary focus for environmental linkages in this system is on impacts of temperature, salinity, and winds on recruitment and juvenile growth. Changes in the abundance of larval food and changes in circulation driven by wind and currents are thought to be key drivers of recruitment variability for all three species. Determining what drives recruitment success requires a combination of empirical fieldwork (determining where and how much spawning and settlement take place) and coupled biophysical models (evaluating how currents, winds, and temperatures affect dispersal and settlement of larvae and consequent recruitment). In addition to circulation and dispersion, model calculations may need to consider spatial patterns of egg production, temporal patterns of hatching, temperature-dependent development, vertical distribution, and mortality (see Incze *et al.*, 2010, and Churchill *et al.*, 2011, for examples that are relevant to this system).

A variety of ecological linkages, natural and artificial, are being studied, including predation of groundfish on herring and juvenile lobsters and predation of herring on groundfish larvae. In addition to predator-prey linkages, the team is studying behavior modification as a result of diminished presence of groundfish predators that may have allowed lobster to expand use of habitat and consequently carrying capacity.

This fishery system is somewhat unusual, though perhaps not unique, in that a key linkage between the fisheries is controlled by humans. The artificial trophic linkage resulting from use of herring bait in quantities (exceeding 50,000 tons

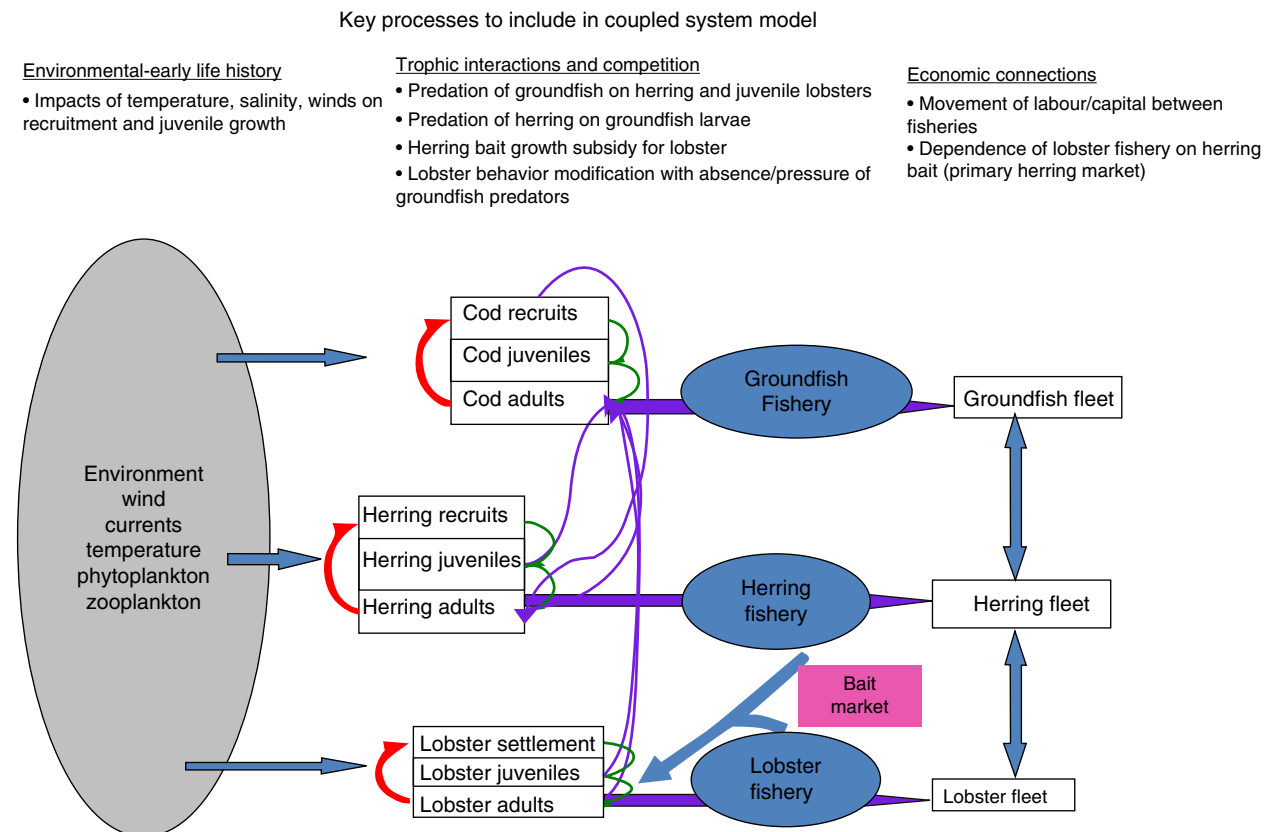

Figure 3 Linkages between lobster, herring, and groundfish fisheries in the Gulf of Maine.

annually in recent years) is thought to be responsible for a substantial increase in productivity of the lobster stock (Grabowski *et al.*, 2010). The way that the lobster fishery is managed substantially alters the amount of herring bait demanded by the fishery, which affects profitability of both fisheries (Holland *et al.*, 2010) and how those profits are distributed (Ryan *et al.*, 2010).

Understanding these linkages among the fisheries and the environment provides useful qualitative insights for resource managers and stakeholders, and it may be possible to use this information to improve single-species models and management advice to account for them as exogenous factors. Ideally, a linked dynamic set of fishery and environmental models will be constructed enabling managers to better understand how changes in one part of the system affect other parts and how best to react or even manipulate the system. In addition to evaluating potential management actions or forecasting future outcomes in the fishery system, models of the system can also be used to determine which variables and processes have the most impact on the system. This knowledge can be used to determine the value of better information and direct research. Ultimately, this information can be used to manage these three key fisheries in a systemwide manner that maximizes the service of provisioning of seafood and the various benefits that flow from that service (e.g., revenues, working waterfronts, community identity).

Coastal Zone Management in Belize

Belize is home to a rich diversity of ocean life, coastal habitats, and the longest barrier reef in the Western hemisphere. Its people are inextricably linked to the marine environment as a source of sustenance, inspiration, economic prosperity, and cultural heritage (Figure 4). Yet rapid development, overfishing, and population growth threaten local marine ecosystems. In

Figure 4 Belize is home to a rich diversity of marine life; its people derive sustenance, inspiration, economic prosperity, and cultural heritage from the marine environment. Mangroves and coral reefs not only provide protection from storms and serve as a draw for international tourism, but also are critical habitats for the spiny lobster, a backbone of commercial and artisanal fisheries. The commercial fishermen in this picture are from a fleet of dugout canoes that work with a traditional sail boat (or “mother ship”) to harvest spiny lobster.

1998, the government created the Coastal Zone Management Authority and Institute (CZMAI) with the objective of developing an integrated management plan to guide sustainable economic growth that is consistent with protection of Belize’s natural heritage. To date, however, CZMAI has lacked the scientific capacity needed to assess trade-offs among various marine uses and to demonstrate potential win–wins where emphasis on one service yields benefits for another.

CZMAI has partnered with the Natural Capital Project to help create a comprehensive coastal zone management plan for Belize. The plan will identify new marine protected areas, locations suitable for coastal development, and strategies such as payments for ecosystem services (PES) and other market mechanisms (e.g., catch shares) to support effective implementation. The partners are using Marine InVEST to forecast how management strategies and future uses of the marine environment will likely affect the benefits that nature brings to people, such as nursery habitat for fisheries, tourism and recreation, coastal protection, and carbon storage. By providing a platform for stakeholder and agency discussions about trade-offs and win–win situations, this information is moving the process beyond sector-specific issues to the development of a defensible plan.

The first step toward developing a coastal zone plan informed by the science of ecosystem services is to identify and map current and potential future uses of marine and coastal environments. Next is to use modeling approaches (in this case, the InVEST decision support tool) to examine how these activities affect the ecosystem services most important to Belizeans. The team is running marine InVEST models, given future scenarios of marine use, to quantify changes in the ecosystem services that are most compelling to stakeholders and government officials. Scenarios under consideration include explorations of how coastal development and no-take areas – in addition to climate change – might affect services, including (1) provision of commercial and artisanal fisheries for lobster; (2) flooding and erosion protection provided by mangroves, corals, and seagrasses; and (3) maintenance of tourism attractions such as snorkeling and diving. Quantitative outputs in biophysical (e.g., biomass of harvested fish, reduction in land flooded or eroded due to mangroves) and economic (e.g., net present value of harvest, avoided damages to property values) units for each service are informing CZMAI’s coastal planning process.

Modeling of ecosystem services in Belize is helping to articulate connections between human activities that are often considered in isolation to align diverse stakeholders around common goals and to make implicit decisions explicit. Ecosystem service modeling results have informed early iterations of the coastal zone plan and will inform the creation of the final plan in 2012.

Protection and Restoration of Reef Habitats in the Coral Triangle

Klein *et al.* (2010) used a combination of quantitative modeling and qualitative information to prioritize strategies for protection and restoration of reef habitats in the coral triangle. The method is designed to allocate a limited budget to management and policy interventions that will abate key threats

affecting marine ecosystem objectives. The approach requires estimates of management costs and opportunity costs of applying alternative actions; and these estimates are user-generated, so they can come from expert judgment, models, or empirical information. The models provide an estimate of the return on investment for different actions so that the relative merits of land- and marine-based interventions on marine ecosystem biodiversity and services can be weighed. This type of practical approach, where a mix of quantitative and expert information is used, allows the users to consider both economic and ecological criteria in a conservation management context. For example, for the ecoregions of the coral triangle, marine-based conservation efforts (e.g., establishment of MPAs, changes in fishing gear types) were often more cost-effective at improving marine ecosystem condition than land-based actions designed to reduce nutrient or sediment runoff.

Putting Offshore Wind in Context in Massachusetts

Like many coastal marine ecosystems, the coast of Massachusetts (US) is crowded with various user groups interested in using a broad range of ecosystem services. Conflicts among sectors in their ability to procure different services from shared, interacting ecosystem resources has prompted calls for the reduction of conflicts through transparent, integrated marine spatial planning. In Massachusetts and elsewhere, offshore wind farms are an emerging, and controversial, ocean use. Numerous wind farms are under litigation or consideration in the state. Large economic gains and “green” energy are purported benefits; impacts on marine mammals and fisheries are some of the potential costs. To explore these issues and inform the dialogue about this new and emerging use of the marine environment, White and colleagues (in press) performed a spatially explicit bioeconomic trade-off analysis among wind energy, fishery, and whale-watching ecosystem services in Massachusetts Bay. They identified optimal planning solutions for wind-energy development that minimize spatial conflicts among sectors and maximize their values. Solutions that considered all three sectors were significantly better than single-sector management outcomes. Solutions were also strongly dependent on the spatial design of the wind farms and the particular fishery examined. This approach of quantifying ecosystem service trade-offs in a crowded, multi-use ecosystem highlights when and how offshore renewable energy may be developed optimally within the complicated contexts of coastal ecosystems.

Conclusions

Marine ecosystems around the globe are under increasing pressure: people rely on them for the delivery of provisioning, regulating, supporting, and cultural ecosystem services. With increasing pressure from increasing and redistributing human populations and from new and emerging uses (e.g., renewable energy), the ability of these systems to sustainably deliver the full range of services that people count on and need is not assured.

Here we have reviewed the services provided by marine environments, discussed some of the potential audiences for information about how changes in marine ecosystems are likely to lead to changes in services, explored critical differences – both in human and scientific contexts – between mapping and modeling ecosystem services on land and at sea, outlined approaches to modeling marine ecosystem services, and described some examples of how these approaches can and are being used in real decision making.

Quantifying, mapping, and valuing marine ecosystem services have the potential to fundamentally change decision making in marine and coastal environments. Making explicit the connections between human activities in one sector and their effects on a broad range of other sectors leads people to think about whole ecosystems and to manage them accordingly. Ultimately, results from marine ecosystem service modeling can help society perceive the critical services oceans and coasts provide, appropriately value marine natural capital, and help human communities make better choices about the use of these life-sustaining environments.

Glossary

Cultural ecosystem services Ecosystems' contributions to the nonmaterial benefits (e.g., capabilities and experiences) that arise from human interactions with ecosystems (Chan *et al.*, 2012).

Ecosystem service An ecological process that creates value for one or more people. For example, the ability of a wetland to remove pollutants from surface and ground water moving through a watershed creates value for society by reducing the amount of money that communities have to spend on water remediation technology and activities.

Ecosystem service value The amount of benefit that an ecosystem service generates for people. The value a service generates will depend on the magnitude of its supply and human demand for the service. For example, animal pollinators can increase the yield and quality of crops. The more nesting habitat and pollinator food the landscape provides the greater the supply of pollinator service on the landscape. The value of increased pollinator abundance will depend on how many crops on the landscape are pollinator dependent and the market or nutritional value of the pollinator-dependent crops grown on the landscape.

Net social benefit When a change in the economy or landscape creates additional societal benefits and costs, the net social benefit of the change is given by the additional societal benefits less the additional societal costs. When the societal benefits generated by a change are greater than societal costs generated by the change, net social benefit is positive and vice versa.

Optimal landscape When land use, land cover, and land management are distributed across a landscape such that it produces the highest level or value of some good, service, or sum of goods or services subject to a series of landscape and economic constraints. For example, we could use a carbon storage and sequestration ecological production function to determine the land use and management pattern across the

landscape that maximizes carbon sequestration over time subject to maintaining a certain level of urban and agricultural production value.

Provisioning ecosystem service A consumable good whose production is at least partly dependent on resources in the ecosystem. Generally, the quality or level of a provisioning service will depend on the extent or quality of various supporting ecological conditions and processes on the landscape. For example, crop production, a provisioning service, tends to increase in the organic carbon content of soil. In this case, organic carbon content is a service that supports a provisioning service.

Public good A pure public good is a good or service that is nonrivalrous and nonexcludable. For example, clean air is a pure public good. A good or service that is nonrivalrous but excludable, like a national park that charges for entrance, is a club good. A good or service that is rivalrous but nonexcludable, like fish in a lake open to the public, is a common property resource.

Regulating ecosystem service An ecological process that provides people value indirectly by mollifying or preventing more extreme or destabilizing conditions on the landscape. For example, by sequestering carbon on the landscape we can mollify the pace of climate change and its expected economic damages.

Spatially explicit ecological production function A mathematical mechanism that translates spatially explicit information on conditions, features, and processes in an ecosystem to some ecological outcome or condition in the ecosystem. For example, a pollinator abundance production function uses data on patterns of land cover, land use, land management, local climate, and biophysical features on a landscape to estimate the abundance of pollinators across the landscape.

Supporting ecosystem service Any ecological process or feature that aids in the quality, level, or duration of another ecosystem service.

Introduction

Ecosystem services are ecological processes and conditions that create value for one or more people (MA, 2005; Boyd and Banzhaf, 2006). Terrestrial ecosystem services include all services produced on land or in fresh water bodies. Ecosystem services include processes that support the production of consumable goods, processes that support and regulate life (e.g., storm surge protection, climate regulation), and

conditions that enhance life (e.g., recreational, esthetic, and spiritual experiences).

Landowners in market economies are financially rewarded for producing goods and services that are sold in markets. Therefore, profit-maximizing landowners are interested in maintaining ecosystem services to the extent that they cost-effectively enhance the production of the goods and services they produce for markets. However, landowners' self-interested land use and management decisions can affect the

production of their neighbors' marketed goods and a wider range of ecosystem services across the landscape. Because landowners are usually not rewarded (or punished) for the impact of their decisions on the production (or destruction) of marketed goods elsewhere on the landscape and most ecosystem services, they are often largely indifferent to these landscape dynamics (Kroeger and Casey, 2007).

Such indifference may not be socially optimal, however. Given that ecosystem services create value for at least one person, society might realize a net benefit from better management of their provision even if the providers of services do not realize a private net benefit from such actions (e.g., Polasky *et al.*, 2011). For example, if adopting less-intensive cropping practices in the upstream reaches of a watershed generates more in ecosystem service value downstream than the loss in net returns on the impacted croplands, then local policy makers can create a net social benefit by paying upstream farmers just enough to make it in their financial interest to adopt these less-intensive cropping practices (Pattanayak *et al.*, 2010). In order to make calculations like this we need methods for accurately modeling and mapping service provision and value across a landscape, whether for current conditions on the landscape or potential conditions in the future.

Ecosystem Service Supply, Demand, and Value

The amount of value that terrestrial ecosystem services provide to people is a function of the magnitude of service supply, the duration of supply, the number of people that benefit from the supply, and how important or valuable the service is to the people that benefit from the supply (Kareiva *et al.*, 2011). The intersection of supply and demand varies greatly across services and landscapes. For example, land use/land cover (LULC) pattern in a river valley can affect the likelihood of flooding in a town downstream. An ecosystem service is created when upstream landowners make decisions on their lands that reduce the risk of flood in the town downriver. The value of this service is determined by how much flood risk reduction is provided and the demand for flood risk reduction in the town. The owners of town land threatened by flooding would be willing to pay money for the service. The more commercially valuable the land that is at risk for flooding, the more the owners of the land value and are willing to pay for flood mitigation services, all else equal (flood insurance would reduce the willingness of landowners to pay for these services). However, how much value the town landowners receive from flood risk mitigation will be limited by the extent of flood-mitigating behavior by landowners above the town. If landowners upstream of the town engage in activities that minimally reduce the risk of flood downstream, then the expected increase in avoided flood damage will be small regardless of the value of the land threatened in town. As the risk of flooding is reduced more and more by actions upstream, the expected avoided damages in the town will increasingly be determined by the commercial value of the threatened land.

For other services, the suppliers and consumers can be the same people. For example, consider a farm planted with crops whose yield increases in animal-pollinator abundance. If the

monetary value of the additional production created by attracting additional pollinators to the farm is greater than the cost of establishing pollinator habitat on the farm, then we would expect a profit-maximizing farmer to establish the necessary habitat. The farmer creates a public good and "external" benefits as well if the pollinators attracted to the farmer's field spillover to neighboring farms with pollinator-dependent crops.

Services and their associated values are comparable on other metrics as well. Some services are rivalrous and excludable whereas other services generate benefits that many people can consume and benefit from. For example, consider the pollination service created by establishing additional pollinator habitat on a farm. The value created by the additional pollinators attracted to the farm by the new habitat is captured by the farm's owner and, in some cases, her immediate neighbors. The benefit is rivalrous (by attracting pollinators to her land the pollinators are not available to other farmers except her immediate neighbors) and excludable (only the farmer and her neighbors capture the value created by the additional habitat). Conversely, when water quality is improved in a public lake it creates benefits for all users of the lake. Further, the benefits are not rivalrous – one person's enjoyment of the clean lake does not prevent another person's enjoyment (it is excludable if there is a fee to enter the park that contains the lake). Because many people benefit from the public good of improved water quality in the lake the total value of this service is likely to be much larger than the total value of the pollinator services that accrue to the farmer and her immediate neighbors.

Further, supply and value provided by a service can decrease or even disappear if service supply reverts back to previous levels or consumers of the service demand less of it. For example, if the commercial value of land in the town downriver decreases, then any reduction in flood risk generated upstream becomes less valuable. Or if the farmer that established pollinator habitat eventually produces a crop that is not animal-pollinator dependent, then the pollinator service previously produced on her farm completely disappears.

Therefore, it is essential that any attempt to model services be able to represent these various dimensions of service supply, demand, and value in general and for the landscape in question in particular. Further, the models need to be sensitive to changes on landscape, whether man-made or natural, so the researcher can predict the ramifications of these changes as mediated through ecosystems and the services they provide. It is the authors' opinion that only spatially explicit production and demand functions exhibit these characteristics. Spatially explicit production functions estimate the supply of ecological processes at all points on the landscape with a mathematical relationship that converts patterns of LULC, land management, biophysical features, geological features, climate, and weather across the landscape into a map of an ecological process, states, or condition. A change in any one of these inputs can change the production of ecological processes, states, or conditions across the landscape. The spatially implicit demand functions determine how valuable the supplies of various ecological processes are. Demand functions are explained by the number of people and pattern of people across the landscape and their willingness to pay for these

services. This production function approach is in contrast to a benefits transfer methodology where the service levels and values provided by a natural feature on a landscape (e.g., a wetland) are based on values the natural feature has been estimated to provide on other landscapes (e.g., Troy and Wilson, 2006). The authors feel that transferred values rarely accurately describe values on the landscape in question given its inevitably unique supply and demand dynamics. Further, it is not clear how transferred values can be accurately modified as conditions on the landscape change.

Reporting Ecosystem Service Supply and Value in Biophysical Terms

To introduce the reader to the concept of ecosystem service modeling with production functions the authors will discuss several terrestrial ecosystem service provision and value models in detail below (space limitations do not allow for an in-depth discussion of all services). However, the authors only briefly discuss the conversion of consumed ecosystem service supply into a monetary value. While it is often very illuminating to convert the consumption of supplied services into a money metric, there may be many instances where biophysical measures of value are sufficient for research or policy questions. For example, a researcher or policy maker interested in determining how much more carbon a landscape can sequester if managed in a certain way will not need to go beyond the models described below. Or a policy maker interested in the trade-off between the volume of wood harvested and the amount of sediment retained on the landscape across various forest management scenarios will find the models discussed here sufficient.

Modeling Ecosystem Service Provision and Value

The authors structure their discussion of ecosystem service modeling using the service taxonomy proposed by the *Millennium Ecosystem Assessment (MA)* (2005). First, the authors discuss provisioning services. Here the authors highlight the provision of agriculture and other consumable goods on the landscape and ways to measure the contribution supporting ecosystem services make to their production. Second, the authors discuss regulating services such as carbon storage and sequestration and storm peak mitigation. Third, the authors touch on the ecosystem processes that support nature-based recreation and the esthetic and spiritual opportunities provided by ecosystems. Finally, the authors focus on the modeling of services that support the provision of the aforementioned consumable goods, regulating services, and cultural experiences.

Because a service can simultaneously contribute to the production of more than one valuable landscape process, service values can be double-counted if a modeler is not careful (Fisher *et al.*, 2009; Boyd and Krupnick, 2009). For example, pollinators support the production of certain crops. Therefore, it would be inappropriate to aggregate the value of agricultural production and the supportive value of pollination on the landscape; the value of pollinators is already part

of agricultural production value. However, it is appropriate to value a supporting service multiple times if it contributes to two or more valuable processes on the landscape. For example, retaining more nitrogen fertilizer on the landscape improves water quality. Therefore, retention of nitrogen on the landscape can decrease the costs of meeting drinking water regulations and improve the recreational fishing, swimming, and boating experiences at local lakes. The avoided water remediation costs and improved recreation experiences can be aggregated and attributed to nutrient retention on the landscape. Proper accounting of the marginal contributions supporting services make to provisioning and regulatory service supply and consumption is particularly important when making claims regarding the monetary value of services produced on the landscape.

Provision of Consumable Goods

Ecological processes contribute to the production of goods that we harvest for consumption. For example, the services that support agricultural production include sediment retention, nutrient cycling in the soil, pollination, and water supply for irrigation. Timber and hydroelectricity are other appropriated goods whose production is supported by ecological processes and like agriculture, tend to be highly managed. Other provisioning services, such as bush meat and medicinal plant production, also rely on various supporting services but tend to be much less managed by humans.

Example: Modeling Crop Production

Crops for food, fiber or fuel are produced with a mix of man-made inputs like seed, fertilizers, pesticides, machinery, and labor, and ecological processes like water supply, nutrient cycling in soil, soil retention, natural pest predators, pollinators, and ecological conditions like soil quality and weather (Swinton *et al.*, 2007). Let Y_{ko} indicate the metric tons of marketable crop k produced in field o . Output Y_{ko} is explained by a vector of man-made inputs applied in field o , σ_o , a vector of ecological processes in field o , θ_o , a vector of ecological conditions in field o , ω_o (e.g., weather), and a vector of past land use in field o , φ_o (e.g., maize production flowing bean production benefits from the nitrogen fixed in the soil by the beans).

$$Y_{ko} = f_{kl(o)}(\sigma_o, \theta_o, \omega_o, \varphi_o) \quad [1]$$

where $f_{kl(o)}$ is the yield function specific to crop k in the landscape l that contains field o , symbolized by $l(o)$. The vector θ_o includes all supporting ecosystem services other than irrigation water which is included in vector σ_o because irrigation water levels in field o are much more controlled than all other agriculture-related supporting services. The function $f_{kl(o)}$ can be estimated statistically using data on the variables found in [1] (e.g., Foley *et al.*, 2011) or can come from crop simulation models like DSSAT, CropWat, EPIC, and APSIM (IBSNAT, 1989; Smith, 1993; Williams, 1995; Keating *et al.*, 2003). The monetary value of Y_{ko} is given by the revenue it generates less production costs or $R_{ko} = p_{kl}Y_{ko} - C_{ko}$ where R_{ko} is the net revenue from producing k on o , p_{kl} is the per ton market price of crop k on landscape l , and C_{ko} is the cost of producing crop k on field o .

As long as field o is used for marketable crop production it will produce a series of output Y . The frequency and magnitude of output over a given time frame are a function of climate and crop choice. For example, in tropical climates a field may be able to produce two crops in a calendar year while a field in more temperate climates can only produce one crop per calendar year. Or a crop may require several years of establishment before a marketable crop is produced. For example, it typically takes 3–4 years after planting for a coffee bush to produce a marketable crop. The net present value (NPV) of the series of output Y on field o is given by the discounted sum of all R_o values.

Most often we assume a farmer will choose crops k and levels of σ_o over time such that they maximize NPV (in some cases, especially in subsistence farming, the objective may be to minimize risk of crop failure). The choices of k and σ_o that maximize the NPV will change as θ_o , ω_o , and φ_o change. See Ghazoul (2007, 2008), Kremen *et al.* (2008), and Nelson *et al.* (2011) for more on farmer decision making given ecosystem service provision on the landscape.

We can use the yield function in eqn [1] and the assumption of a profit-maximizing farmer to determine the marginal productive value of the ecosystem services that support agricultural production on field o . For example, imagine changes on the landscape increase the field o 's animal-pollinator abundance (a change in θ_o) and access to water during the growing season. Suppose the provision of all other supporting services and ecological conditions on field o do not change. Given the change in θ_o and water availability, field o 's farmer reassesses her choice of k and levels of σ_o . Assume before the change on the landscape the farmer of o always planted k and k produced one crop per calendar year. Now suppose after the change in θ_o and water availability the farmer of o finds it in her best financial interest to choose a more animal-pollinator- and irrigation-dependent crop. Let $\hat{k}$ and $\hat{\sigma}_o$ indicate the farmer's production and managed input choices (including irrigation water applied) given the change in θ_o , represented by $\hat{\theta}_o$, and water availability. Assuming $\hat{k}$ is also only produced once per calendar year on field o , the annual marginal productive value of the increases in pollinator abundance and water availability is given by

$$\hat{V}_o = f_{kl(o)}(\hat{\sigma}_o, \hat{\theta}_o, \omega_o, \varphi_o) - f_{kl(o)}(\sigma_o, \theta_o, \omega_o, \varphi_o) \quad [2]$$

where $\hat{V}_o$ is measured in metric tons. Ignoring crop and food waste (which is substantial; see Parfitt *et al.*, 2010), all of $\hat{V}_o$ is valuable to society, although the consumers who benefit from the additional production of k on field o may reside far from it. The annual net monetary value of the change in pollinator abundance and water availability in field o is equal to

$$\begin{aligned} \hat{R}_o = & (p_{kl} f_{kl(o)}(\hat{\sigma}_o, \hat{\theta}_o, \omega_o, \varphi_o) - C_{k_o}) \\ & - (p_{kl} f_{kl(o)}(\sigma_o, \theta_o, \omega_o, \varphi_o) - C_{k_o}) \end{aligned} \quad [3]$$

All else equal, services that support agriculture are more valuable monetarily on the landscapes that generate crops that are more highly valued in the market and that interact more efficiently with managed inputs. An alternative method for placing a value on the change in the supply of services that

support agriculture is to determine the impact of the change on calorie or micronutrient production.

This modeling framework can also be used to estimate how much a farmer would need to be paid to adopt management practices that increased ecosystem service supply on the landscape (i.e., payments for ecosystem services). For example, let $\hat{k}$ and $\hat{\sigma}_o$ indicate the crop and managed input choices that the policy maker would like the farmer of field o to adopt for perpetuity. Assume the climate on o is such that only one crop can be produced on the field per year no matter what the choice of k or managed inputs is. Let s be the annual payment given to the farmer for adopting $\hat{k}$ and $\hat{\sigma}_o$. Accepting the payment of s and its production restrictions is only optimal for the farmer of field o if the value of s is such that

$$\begin{aligned} \sum_{t=0}^{\infty} \frac{s + (p_{kl} f_{kl(o)}(\hat{\sigma}_o, \hat{\theta}_{ot}, \omega_{ot}, \varphi_{ot}) - C_{k_{ot}})}{(1+r)^t} \\ \geq \sum_{t=0}^{\infty} \frac{p_{k_t} f_{k_t l(o)}(\sigma_{ot}^*, \theta_{ot}^*, \omega_{ot}, \varphi_{ot}) - C_{k_{ot}}}{(1+r)^t} \end{aligned} \quad [4]$$

where r is the annual discount rate and k_t^* , σ_{ot}^* , and θ_{ot}^* for all years $t=0,1,2,\dots$ indicate the nonsubsidized cropland and management choices, respectively, that maximize the discounted NPV of returns to farming on field o . In words, the value of s needs to be large enough so choosing $\hat{k}$ and $\hat{\sigma}_o$ for perpetuity generates as much expected NPV as not taking s and optimizing the NPV of net revenues on field o .

Other Provisioning Services

The supply of several other provisioning services is heavily dependent on the property rights structure in the ecosystem or resource that provides the good. For example, if a forest is privately held and used primarily for timber production, it is reasonable for a modeler to expect that the owner of the forest manages and extracts timber from the forest in such a way that the NPV of timber harvests over time is maximized (see Nelson *et al.* (2011) for an example of such a model). In this case, NPV is maximized by always keeping a portion of the resource *in situ* for future harvest. This allows the owner to take advantage of growing timber and its associated growth in value. Ecosystem services that support timber production include soil nutrient cycling, pest control, and fire regime management. Fresh water fisheries with private property rights are described by the same harvest dynamics as a private forest; simply substitute the harvest of wood with the harvest of fish. Improved water quality and sediment retention on the landscape support the service of fish production in fresh water bodies.

When resources are privately controlled the entire resource stock at any given time, that which is harvested plus that left *in situ*, provides marketable value to the owner of the resource. Therefore, the ecosystem services that support the growth and health of privately controlled resources tend to be maintained over time. The marginal productive value and NPV of changes in services that support timber and fish production can be determined in a manner similar to that of the services that support agricultural production (see eqn [2]).

If an owner of a resource cannot prevent poaching of its stock or property rights are not well defined or do not exist at

all, then the resource is described by open access (Bromley, 1991). Open access systems are defined by intense harvesting effort because there is no incentive among harvesters to forego harvest of some stock in order to let it and its value grow; someone else will take it in the meantime. See Lopez-Feldman and Wilen (2008), Robinson *et al.* (2008), and Nelson *et al.* (2011) for examples of open access harvest models. Eventually harvest effort for the open access resource will fall as low stock levels dramatically increase the harvester's opportunity cost of resource collection. Much nontimber-forest product (NTFP) harvest in developing countries can be modeled as an open access system (Ticktin and Shackleton, 2011). Again we assume the entire harvest of products from open access systems provide value to harvesters and therefore, society. Unlike the closed access systems, however, *in situ* stock does not provide marketable value to anyone (however, *in situ* stock can provide other service values such as carbon storage). Further, the consumptive value that an open access resource provides over time diminishes quickly as the resource's stock falls. Therefore, the value of services that aid stock production in open access systems will decrease over time. One method for preventing the collapse in resource stocks and value under open access is to establish property rights over the system. This does not necessarily mean privatizing the resource. Ostrom (1999) gives examples of resources under communal property right structures that have maintained sustainable harvests over time.

Another consumptive good whose supply is aided by ecological processes is hydroelectric power. Energy is created when water yielded in a catchment (precipitation less evapotranspiration) is routed through a turbine. The greater the water yield upstream of the turbine and the less that this yield is diverted for other uses, the greater the potential for this water to drive the turbine. Hydrological production at a dam is even more valuable if the reservoir behind the dam does not have to be dredged often to remove deposited sediment. Therefore, the more sediment the landscape can capture upstream of a dam the more net revenue the hydroelectric turbine at the dam provides. Electricity provided when a flowing river or stream passes through a turbine (run of the river systems) is much more variable than electricity provided by dams. Dam managers have the ability to set their preferred production schedule by opening and closing the dam. The better models of hydroelectric power production at dams include this element of manager decision making. Conversely, electricity production at run of the river systems will fall as stream volume falls either due to weather or water use upstream; electricity production at these turbines is relatively management free. However, unlike dam models, which can use seasonal or annual water volume data, run of the river system models requires seasonal or even finer temporal data to simulate undulating flows in the river or stream of interest. See Gibbons (1986), Edwards (2003), and Mendoza *et al.* (2011) for more on hydroelectric power models. The impact of a change in the provision of water yield or sediment retention on hydroelectric power generation and its net revenues provides some information on the value of these supporting services.

Clean fresh water for drinking and other direct human consumption is another vital good whose supply is affected by ecosystems. The supply of fresh water in a region is largely determined by a climate-driven water balance. However, what

portion of this supply can be safely consumed by humans without extensive remediation will largely be determined by landscape processes. As water flows across a landscape and through its substrate towards water bodies it will bring pollutants and sediment with it. The more such pollutants are deposited into the landscape's sources of fresh water the more landscape's regulators have to pay to clean the water or in the absence of effective regulation, the greater the likelihood that people will become sick from using the water for drinking, washing, and bathing. Therefore, the more pollutants that the landscape can trap or retain the more value created, either in the form of reduced water purification costs or reduced health damages. The value of the pollutant and sediment retention services is equal to the value of any purification costs or health damages avoided. For example, if pollutant retention on a potential LULC pattern prevents one death and 10 illnesses per year compared to a baseline LULC pattern on the landscape, then the value of additional pollutant retention on the alternative landscape is one death and 10 illnesses. If additional pollutant retention on an alternative landscape does not prevent any deaths or illnesses and does not reduce any regulatory costs, then from a clean fresh water perspective, this supporting service of nutrient retention is valueless.

Regulatory Services

Regulatory services are the processes that provide societal value indirectly by mollifying or preventing more extreme or destabilizing conditions on the landscape. For example, flood control reduces the expected damages after a weather event that introduces an excessive quantity of water on the landscape quickly. Below we highlight several regulatory services and approaches to modeling them. Besides the highlighted services, ecosystems can also regulate the concentration of air pollutants such as nitrous oxides, ground-level ozone, and volatile organic chemicals (Pataki *et al.*, 2011) and help control certain diseases such as malaria (Foley *et al.*, 2005).

Example: Carbon Storage and Sequestration

Over time biomass and soils can capture and store carbon that would otherwise bind with oxygen elements and reside in the atmosphere or ocean as the greenhouse gas (GHG) carbon dioxide (CO₂). By increasing the rate of carbon taken-up by plants and soil and reducing the disturbance of pools of biomass and soil carbon that already exist, even if just temporarily, the process of human-induced climate change and increased ocean acidification can be slowed (Lal, 2004). And because damage to the globe's economies and the environment is expected to increase in climate change, increased carbon sequestration and storage above some baseline expectation of sequestration and storage (additional sequestration and storage) should delay or permanently reduce the path of expected damages. Even just delaying economic damages is valuable because it gives societies more time to adapt and prepare for climate change impacts.

A model of carbon storage and sequestration accounts for the transfer of carbon from one pool to another, including the atmospheric pool, over time. The amount of carbon sequestered in a land parcel over some time frame is the difference in the parcel's storage at the beginning and end of the time frame.

Assume for now that carbon storage levels do not change in parcel x until there is a LULC change on x . Let C_{ixjkt} indicate the amount of carbon stored in pool i on parcel x that is in LULC k but transitioned from LULC j t years ago. The amount of carbon sequestered on parcel x since the transition is given by

$$\Delta C_{xjkt} = C_{axjkt} + C_{bxjkt} + C_{sxjkt} + C_{hxjkt} - C_{axj} - C_{bxj} - C_{sxj} - C_{hxj} \quad [5]$$

where $i=a, b, s$ and h indicate the aboveground biomass, belowground biomass, soil, and other carbon storage pools, respectively, and C_{ixj} is the carbon stored in pool i on parcel x in LULC j . In this setting, if LULC does not change on x then after t years sequestration in x is equal to 0. This modeling limitation can be relaxed by making the C variables in eqn [5] a function of land management, climate, and larger landscape dynamics as well. In this case, a change in LULC, land management, climate, and larger landscape dynamics in and around x would engender sequestration. $C_{ixjkt} > C_{ixj}$ if the change in LULC causes pool i to gain more in carbon from other pools (including the atmosphere pool) than it loses to other pools and vice versa. The magnitude of C_{ixjkt} can be determined with a function that is explained by x 's biophysical features, LULC j and its features, LULC k and its features, j to k transition dynamics, time, and the climate in x (e.g., *Metherell et al., 1993*).

A simpler version of eqn [5] assumes that each carbon pool in a parcel that transitions to LULC k will eventually reach a steady-state level of storage where steady-state levels and time to reach steady state are not dependent on any features specific to x or the previous LULC. Let $\hat{C}_{ik}$ be carbon pool i 's steady-state level in LULC k and T_{ik} be the years it takes pool i to reach its steady state after a transition to LULC k (note that $\hat{C}_{ik}$ and T_{ik} are not a function of x or LULC j). In this case, eqn [5] becomes

$$\Delta C_{xjkt} = t \left[\frac{\hat{C}_{ak} - C_{axj}}{T_{ak}} + \frac{\hat{C}_{bk} - C_{bxj}}{T_{bk}} + \frac{\hat{C}_{sk} - C_{sxj}}{T_{sk}} + \frac{\hat{C}_{ok} - C_{oxj}}{T_{ok}} \right] \quad [6]$$

If $t > T_{ak}$ then $t[\hat{C}_{ij} - C_{ixk}]/T_{ak}$ is equal to $\hat{C}_{ik} - C_{ixj}$. In eqn [6] the sequestration rate in each pool is constant. This is a modeling simplification as field evidence suggests that terrestrial carbon sequestration follows a nonlinear path over time (e.g., *Schlesinger, 1990*). Finally, if the modeler lacks information on the level of pool storage in parcel x just before the transition from LULC j to k , then she could assume steady-state storage just before the transition as well. In this case, each storage parameter C_{ixj} in eqn [6] is set equal to its steady-state level, $\hat{C}_{ij}$.

A landscape scenario would indicate the LULC and management transitions and their timing for each parcel on the landscape. For example, suppose a scenario indicated that parcel x would transition from LULC j to LULC k 5 years after the beginning of the modeling time frame and then from LULC k to LULC q 19 years after the beginning of the modeling time frame. Suppose the scenario time frame is 40 years. According to the methodology above, during the first 5 years of the scenario there would be no change in carbon storage on the parcel, the change in storage on x from year 5 to year 19 (where $t=14$) would be given by eqn [5] (or [6]) where C_{ixj}

(or $\hat{C}_{ij}$) is the initial carbon stored in pool i on x given LULC j , and the change in storage on the parcel from year 19 to year 40 (where $t=21$) would be given by eqn [5] (or [6]) where C_{ixj} (or $\hat{C}_{ik}$) is equal to $C_{ixjk,14}$ (or $14[\hat{C}_{ik} - C_{ixj}]/T_{ik}$ or $14[\hat{C}_{ik} - \hat{C}_{ij}]/T_{ik}$). Over the entire scenario time frame sequestration in parcel x is given by $\Delta C_{xjk,14} + \Delta C_{xkq,21}$.

The portion of sequestration in parcel x that provides value to society is given by the sequestration that is additional compared to some baseline sequestration rate. For example, assume the changes in x described above are motivated by a landscape-wide policy of paying landowners for additional carbon sequestration. Further, suppose in the absence of this policy the expected path of LULC transition on x is LULC j to LULC k 10 years after the beginning of the modeling time frame and no changes thereafter. In the baseline case, sequestration on x over the 40-year modeling time frame is equal to $\Delta C_{xjk,30}$. The term $\Delta C_{xjk,14} + \Delta C_{xkq,21} - \Delta C_{xjk,30}$ gives the additional sequestration on x due to the policy. Because every unit of additional sequestration or storage, even if just temporary, no matter where it occurs, delays expected damages across the globe, all additional sequestration is valuable. If the additional tonnage term is negative then the policy has increased economic damage vis-à-vis the baseline.

The proposed approach to carbon storage and sequestration described above ignores several fundamental carbon storage dynamics present in all managed and unmanaged ecosystems. First, the amount of carbon stored in a parcel is in continual flux due to vegetation growth and decay, organic matter accumulation in the soil, and climatic variability. Several models are well suited to track this continual change. The CENTURY Soil Organic Matter Model (*Metherell et al., 1993*) continually tracks carbon dynamics in soil and, despite its name, in biomass as well. Dynamic vegetation models simulate vegetation patterns, and associated carbon dynamics, on the landscape as a function of land use and climate (e.g., *Bachelet et al., 2001*; *Sitch et al., 2003*). These dynamic vegetation models are particularly useful for predicting the effects of climate change on the terrestrial carbon cycle. A second carbon storage dynamics ignored in the model described above is the long-term storage of carbon in biomass removed from the landscape. For example, wood waste and products made from harvested wood can store captured carbon for up to 100 years (*Smith et al., 2006*). Such harvested wood product or waste pools could be added to a carbon storage and sequestration model (*Conte et al., 2011*). Finally, the model proposed above does not account for the annual flux in the GHGs of nitrous oxide (N_2O) and methane (CH_4) from managed land. N_2O is a byproduct of fertilizer use on agricultural fields and traps heat 298 times more effectively than CO_2 . CH_4 , a byproduct of manure, livestock flatulence, and rice paddy and wetland dynamics, traps heat about 20 times more effectively than CO_2 . See *Robertson and Grace (2004)* for more on the emissions of carbon, N_2O , CH_4 , and other GHGs from agricultural fields.

Example: Storm Peak Management

LULC and land management practices in a watershed affect the dynamics of river or stream height downstream after a small to midsize storm event. (A graph that gives the timing of river heights downstream after a storm even is known as a

hydrograph.) For example, LULC and land management changes upstream of a town can reduce the expected peak height of a storm surge in the town. If this reduction in the surge's peak height means less damage in the town after a storm event than it would have been otherwise, then the landscape has provided flood mitigation service. Storm peak and flooding are among the most challenging hydrologic and hydraulic processes to model at the watershed scale. Multiple factors affect how a watershed responds to a specific storm event. A storm peak mitigation model proposed by Ennaanay *et al.* (2011) is composed of three modules. In the first module, Ennaanay *et al.* (2011) use geographic information systems (GIS) software to generate a hydrograph for a downslope point (e.g., a town on a river or stream) given a specific small to medium storm event with uniform depth and duration across the landscape (LULC and land management can do very little to mitigate downriver flooding after very large storm events). The initial module first determines how much of the precipitation runs off each parcel (as opposed to being retained by the parcel's soil and vegetation) upslope of the point of interest. A parcel's excess precipitation or storm runoff is then routed downslope according to an elevation map where some runoff can be retained in wetlands and other depressions with available storage. Any remaining runoff that drains into the watershed's river and stream system will eventually reach the downslope point of interest. The time needed for a parcel's runoff to reach the destination point is found by summing the amount of time the runoff needs to traverse each parcel en route to its drainage point and the subsequent time of travel in the river or stream system to the point of interest. Travel time across the landscape is a function of its roughness and slope where roughness is a LULC and land management characteristic. The first module ends by creating a hydrograph for the point of interest and a map that indicates how long it takes each parcel's runoff to reach the point of interest. In general, the more dissimilar runoff delivery timing is across the parcels upslope of the point of interest, the lower the storm peak is at the point of interest.

The second module of the model proposed by Ennaanay *et al.* (2011) determines how the peak volume will spread beyond the point of interest's channel segment, if at all, after the storm event. For example, if the storm peak of the hydrograph indicates that 100 m³ of water is expected to overflow a stream's banks at the town of interest, then the module delineates what area and to what depth the excess water will flood. The third module uses this flooding information to calculate flooding damage associated with the storm peak.

Similar to the carbon sequestration and storage model, the supply of storm peak mitigation (the reduction of the hydrograph at its highest point) is determined against a baseline case. First, a baseline landscape is used to create the hydrograph for a particular storm event at the point of interest. Then an alternative landscape is evaluated with the same storm event and the same point of interest. The difference in expected flood damage at the point of interest given the alternative landscape represents how much avoided flood damage the alternative LULC and land management pattern provides. For example, suppose the alternative landscape

reduces the height of the storm peak such that 50 m³ less water will flood the point of interest. Therefore, the alternative landscape has generated 50 m³ of avoided flood water at the point of interest. The ultimate value of this storm peak mitigation will depend on the monetary value of the land that will be affected by flooding and the reduction in damages, if any, from marginally less flood water volume.

Cultural Ecosystem Services

Ecosystems also provide "nature," a landscape attribute that enhances outdoor recreation, esthetic experiences, and, for many people, provides a larger meaning and purpose to life. While models for the supply and use of nature-based recreation services and some esthetic services are well developed, the ability to model the spiritual values a landscape provides is limited.

Example: Nature-Based Recreation

The first step in nature-based recreation modeling is to collect data on the number of visits a representative population makes to the various nature-based recreation sites on the landscape. If possible, the visit data should be complemented with the representative population's demographics and their costs of traveling to and remaining in the site for a period of time (both out-of-pocket and opportunity costs). Second, the researcher collects information on the amenities found at the visited sites, both natural and man-made. With this dataset the researcher can build a statistical model that predicts the change in the number of visits to the various sites as a function of changes in natural amenities at one or more of the sites (Phaneuf and Smith, 2005). Generally, as the condition of the natural amenities at a site improves (more water, cleaner water, cleaner air, etc.), all else equal, more visits are made to the site and more consumer satisfaction is generated. The structure of the statistical model allows the researcher to isolate visitor response to and the consumer value generated by an improvement in the natural amenity. This value can then be distributed among the ecosystem services that support the natural amenity's improvement.

These recreational models tend to find that the demand for nature-based recreation services increases as people on the landscape become wealthier and can afford more and longer trips. Therefore, nature-based recreation visits have increased around the world as it has gotten wealthier (Pergams and Zaradic, 2006, 2008; Balmford *et al.*, 2009). Further, sites that are easily accessible to many people tend to generate more visits than other sites, all else equal (Bateman *et al.*, 1996). Therefore, services that enhance nature-based recreation at sites that are easily accessible and are attractive to a wealthier clientele are particularly valuable, at least from a monetary perspective, all else equal (e.g., Egan *et al.*, 2009; Vesterinen *et al.*, 2010).

Example: Esthetic Services

Natural vistas provide pleasure to people. Viewing natural vistas may be a primary motivation for a nature-based recreation and the quality of the view at recreation sites should be used to help explain visits to the site (*see* Example:

Nature-Based Recreation). In addition, people may be willing to pay more for homes that have generous viewsheds dominated by natural features such as trees and water bodies (Cavailhès *et al.*, 2009). With the appropriate land and building elevation and land cover maps, GIS software can estimate the land features that compose a home's viewshed. The value a viewshed adds to a home can be estimated with statistical techniques (Hanley and Barbier, 2009). For example, US homes with large natural viewsheds have been estimated to be worth thousands more dollars than comparable homes without such views (Sander and Polasky, 2009). The additional home value due to more extensive natural vistas can then be distributed among the ecosystem services that support the quality of this view. See Tallis *et al.* (2011) and Johnson *et al.* (2010) for examples of viewshed models.

Other Cultural and Spiritual Services

Other cultural and spiritual services include the "nonmaterial benefits people obtain from ecosystems through spiritual enrichment, cognitive development, reflection..., including, e.g., knowledge systems, social relations..." (MA, 2005, p. 894). Such cultural and spiritual experiences do not readily lend themselves to measurement. However, methods for mapping or ranking cultural and spiritual sites on a landscape have been proposed (Chan *et al.*, 2012). For example, the nutritional and economic value of subsistence animal and plant harvesting in indigenous groups (a cultural experience) can be estimated to obtain a lower bound on the value provided by the ecosystem services that support the growth of harvested natural resources (Chan *et al.*, 2012).

Supporting Services

As exemplified above, most provisioning, regulating, cultural, and spiritual services rely heavily on more fundamental supporting services. For example, in the agricultural model described above we highlighted two services that support agricultural production, pollination, and water supply. Hydro-power production is supported by the ecological processes of water yield and sediment retention. The soil's ability to sequester and store carbon increases as animal diversity and abundance in the soil increases (Six *et al.*, 2006). Other ecological processes that support valuable services are nutrient cycling in soils (Giller *et al.*, 1997) and in-stream processes such as water temperature and turbidity. The authors describe the modeling of several supporting services in detail below.

Example: Animal Pollination

Pollinating animals can increase the yield, quality, and stability of the production of many crops, including almond, cacao, canola, coffee, sunflower, tomato, and watermelon. Klein *et al.* (2007) estimate 68% of globally important crops benefit from animal pollination. Gallai *et al.* (2011) find pollinators add approximately \$200 billion each year to the value of agricultural production across the world. For pollinators foraging on a landscape, crops may just be one of several sources of food or floral resources. Further, most animal-pollinated crops are better adapted to interact with certain types of pollinators than others. Therefore, how much an animal-pollinated crop will

benefit from pollinators on the landscape will be a function of the abundance and spatial location of other floral resources on the landscape, the distance between the field and pollinator nesting sites (pollinators can only fly so far when foraging; Westrich, 1996; Williams and Kremen, 2007), and pollinator-crop compatibility.

Vital to the crop pollinating process is the establishment of pollinator nests on the landscape. Nests are only established on certain types of habitat. Further, pollinators are more likely to establish nests in areas that have close-by floral resources at times they are not hibernating. A model of crop pollination, therefore, can be explained by the relationship between land cover and nest habitat, the location of farms of interest in relation to potential nesting sites, the crops grown on the farms, the temporal and spatial pattern of all floral resources on the landscape, the ability of pollinators to disperse over the landscape, and the dose-response effect of each crop-pollinator combination.

Many of these features are in a pollinator service model proposed by Lonsdorf *et al.* (2009). In the model, the abundance of pollinators at each location in a landscape is determined by the location's suitability for nesting and its accessible floral resources (Kremen *et al.*, 2007). In this model, location x 's accessible floral resources include those immediately at x and those on the surrounding landscape, where those resources not at x are discounted by a distance decay function. The model's output is a map of expected pollinator abundance with higher density in locations with better nesting habitat, greater accessibility to floral resources, and that host pollinators that are willing and able to travel longer distances to forage.

The foraging habitat accessible to pollinators nesting at x is given by HF_x ,

$$HF_x = \sum_{m=1}^M F_m e^{(-D_{mx}/\alpha)} \bigg/ \sum_{m=1}^M e^{(-D_{mk}/\alpha)} \quad [7]$$

where F_m represents the relative amount of floral resource available at location m (the series of all locations on the landscape is indexed by $m=1, \dots, M$ where location x is part of the series), D_{mx} is the Euclidean distance between location m and x , and α represents the distance a pollinator will travel to forage (Greenleaf *et al.*, 2007; Gathmann and Tschamtkke, 2002). The abundance/quality of floral resources at site m , F_m , ranges between 0 and 1, where 1 is the highest possible quality; values are assigned according to m 's LULC. In eqn [7] the foraging frequency in location m by pollinators nesting in x declines exponentially with distance between x and m (Cresswell *et al.*, 2000). The model assumes that pollinators forage in all directions from x with equal probability.

Relative pollinator abundance at location x is limited by x 's nesting and accessible floral resources; if either one is completely absent at x that pollinator abundance at x , given by P_x , is equal to 0

$$P_x = HF_x HN_x \quad [8]$$

where HN_x gives nesting habitat suitability at x on a 0–1 scale. In this model HN_x is completely determined by x 's LULC. Nesting suitability is assigned to each LULC according to existing data or expert opinion. We can think of P_x as the

pattern of pollinating service supply on the landscape. How useful the supply of pollinators across the landscape will be to humans depends on what types of crops are grown on the landscape and where these crops are grown.

Crop fields surrounded by locations with higher P values should experience higher levels of pollinator visits than crop fields surrounded by locations with lower P values, all else equal. Let $o = 1, \dots, O$ index crop field locations on the landscape. The fraction of pollinator visits to farm o from location x is given by

$$P_{ox} = P_x e^{(-D_{ox}/\alpha)} / \sum_{m=1}^M e^{(-D_{om}/\alpha)} \quad [9]$$

where D_{ox} (or D_{om}) is the distance between nesting location x (or m) and field o . The numerator of eqn [9] represents the distance-weighted proportion of the pollinators from x that forage on o and the denominator is a scalar that normalizes this contribution by the total area within foraging distance to farm (Winfree *et al.*, 2005). The total pollinator abundance on field o , P_o , is simply the sum over all nesting locations on the landscape, including location x ,

$$P_o = \sum_{m=1}^M P_{om} \quad [10]$$

P_o from eqn [10] can be part of the θ_o vector of supporting agricultural inputs from eqn [1] where P_o will have no effect on yield if the crops grown on o are not animal pollinated.

For modelers not interested in using the agricultural yield model already introduced above, Lonsdorf *et al.* (2009) propose a simple saturating function to translate the relative abundance of pollinators on farms into an expected yield. Expected crop k yield on field o is given by Y_{ko} ,

$$Y_{ok} = \bar{Y}_{ko} [(1 - v_k) + v_k (P_o / P_o + \lambda_k)] \quad [11]$$

where $\bar{Y}_{ko}$ is the expected yield of crop k on field o assuming pollination, either animal or wind-aided, is not a limiting factor in crop growth, and v_k represents the proportion of total crop k 's yield attributable to wild pollination (i.e., v_k is equal to 1 if k is an obligately outcrossing crop and equal to 0 if k is wind pollinated). The yield $\bar{Y}_{ko}$ can be set equal to the observed yields of k in o 's landscape in the cases where researchers know that pollination vectors, either animals or wind, are abundant. The term λ_k in eqn [11] is a half-saturation constant and represents the abundance of pollinators required to reach 50% of pollinator-dependent yield. According to eqn [11] yield for pollinator-dependent crop k ($v_k > 0$) increases as pollinator abundance gets larger (Greenleaf and Kremen, 2006). Equation [11] also indicates that strongly animal-pollinator-dependent crops (k where $v_k \gg 0$) require significant pollinator abundance to yield near their maximum capacity (Allsopp *et al.*, 2008).

The fraction of additional P_o that is valuable to humans is equal to the partial derivative of Y_{ko} with respect to a small change in P_o ,

$$\bar{Y}_{ko} v_k \lambda_k / (P_o + \lambda_k)^2 \quad [12]$$

where P_o in (12) is equal to the level of P_o before its change. In words, the positive productive value of additional pollinator abundance in o , v_{ko} , falls. The net monetary value of a small change in P_o is equal to the marginal value given by eqn [12] times the market price of k (assuming the cost of production does not change given a small change in P_o). The net monetary value of an additional unit of P_o will be higher, all else equal, for more profitable crops. Alternative measures of value, for example, the incremental nutritional value of food produced, will be higher, all else equal, for increases in P_o on fields with more nutritional crops.

The Lonsdorf *et al.* (2009) model has several shortcomings. First, the model does not distinguish among pollinators; all species are represented by a composite pollinator. Second, while the modeler can use F_m to define floral resource preference in the representative pollinator, the pollinators uniformly distribute from the nesting site instead of concentrating at locations on the landscape with preferred resources. See Lonsdorf *et al.* (2011) for a model that addresses some of these limitations.

Example: Nutrient Retention

Pollution produced on a landscape can be transported by surface water runoff into the landscape's water bodies. Such pollution affects the landscape's supply of clean fresh water for human consumption, the abundance of fish and other water life we harvest for food, and the quality of human recreational experiences. Water quality models simulate the transport of pollutants across the landscape to a water outlet. These models typically indicate how land use and management practices at the pixel or hydrologic response unit (HRU; subunits within a watershed) affect water, pollution, and sediment yields at the mouth of a watershed. The most complex water quality models produce time-continuous output of pollutant loadings and require daily weather data along with input data on vegetation, soil properties, and physiography. The Soil and Water Assessment Tool (SWAT) is an example of such a model (Gassman *et al.*, 2007). This tool is remarkable for its ability to model processes such as sediment, nutrient, and pesticide loadings into the stream channel at daily time steps. However, such fine-grain output mandates very detailed sets of data that can be difficult and time consuming to collect. Further, substantial postprocessing time is needed to convert SWAT output to ecosystem service provision and use (Vigerstol and Aukema, 2011). Variable Infiltration Capacity and SPARROW are other hydrological tools that can be used to inform water ecosystem service research and planning.

In a water quality model proposed in Conte *et al.* (2011) nitrogen (N) and phosphorus (P) loadings at a watershed's outlet are calculated on an annual basis instead of a daily or monthly basis. Unlike SWAT and other more complex process models, this rather simple model assigns export coefficients for N and P ($\text{kg ha}^{-1} \text{ yr}^{-1}$) and retention efficiencies to each parcel on the landscape according to its LULC type instead of being determined by soil and physiography characteristics specific to the parcel. In the Conte *et al.* (2011) approach, a LULC's annual export values are based on typical or average nutrient transformation processes that take place in the LULC's soil and vegetation. The export coefficient on each

parcel in the watershed is then combined with each parcel's expected annual water yield to determine annual potential nutrient yield from each parcel. Parcel-level nutrient yields or loads are then routed through downslope parcels to the watershed's mouth. As the water and its nutrient load travels across the landscape some of the load will be captured and retained by intermediate parcels. There is no in-stream cycling of nutrients in the model, so the removal and storage of nutrients is limited to the landscape. The model reports total annual loading of each nutrient at the watershed's mouth.

The supporting service modeled by [Conte et al. \(2011\)](#) and derivable from SWAT is nutrient retention. The more pollutant retained on the landscape, the cleaner the water, and the more valuable the provisioning and regulating services the landscape's water supports. Further, it reduces the need for costly remediation in water systems and wells in order to meet some regulatory pollution standard, or if standards are not applicable, reduces the human mortality and morbidity associated with excessive nutrient pollution. The supply of nutrient retention on an alternative LULC pattern is defined against a baseline pattern (e.g., current or business as usual conditions). The additional retention created on the alternative landscape represents the alternative scenario's supply of this supporting service. The portion of this additional retention that increases the value of provisioning or regulating services and damages avoided represents the usefulness or value of the additional nutrient retention.

Accounting for Uncertainty in Ecosystem Service Provision and Value

The versions of the models presented above only explain expected results. However, ecosystem service provision and value outcomes are highly uncertain for two reasons. First, provision and value vary because of the inherent randomness of nature, human behavior, and technological progress ([Rotmans and van Asselt, 2001](#)). Modelers can attempt to account for this type of uncertainty by systematically varying model input and parameter values (e.g., experimenting with biomass growth rates in a carbon sequestration model) and assumptions regarding human behavior (e.g., farmers are not profit maximizers and instead make decisions according to a goal of minimizing risk of crop failure) and reporting the potential range and likelihood of outcomes. Inexactness, ignorance, and indeterminacy add another degree of uncertainty to modeled results ([Rotmans and van Asselt, 2001](#)). For example, several recent studies demonstrate that soil organic carbon levels in an area are determined by a complex mix of ecological variables that are hard to understand let alone model (e.g., [Dlugoff et al., 2010](#); [Syswerda et al., 2011](#); [Rumpel and Kogel-Knabner, 2010](#); [Powlson et al., 2011](#)). Our ignorance of ecological processes is particularly problematic when trying to understand and model threshold effects and nonlinearities in ecosystem processes. Evaluating service provision and value on a landscape with disparate modeling approaches is one way to begin confronting indeterminacy issues in ecosystem service modeling. If all or most models predict the same direction and magnitude of change in provision and value, then greater certainty can be attached to the predicted outcomes.

Cost-effective Ecosystem Service Provision and Value

Ecosystem service models are often used to estimate the impact of projected LULC, land management, and climate change on service supply and value. However, we can also use ecosystem service models and conventional market return data to describe the optimal use of a landscape when the objective is to maximize the provision of one or more services subject to some economic constraint. To illustrate this point we consider the market returns to changing LULC and land management in the Seven Mile Creek, Minnesota, USA, watershed in order to increase the rate of P retention and carbon sequestration (the 9531 ha Seven Mile Creek watershed is in the Minnesota River Basin). In this analysis every agricultural parcel in a HRU, typically 2.5 ha, can stay in their current uses (the baseline) or all can convert to switchgrass production, prairie plant production, or timber and pulp production or remain in conventional row crop or pasture production but with lower P application rates. Switchgrass and prairie plants are marketable because they could be used as biomass for electricity generation or the feedstock of liquid fuel ([Daniel et al., 2003](#)). SWAT is used to model the effect of LULC and land management pattern across the watershed on annual loading of P (kg ha^{-1}) into the Minnesota River. A version of the carbon storage and sequestration model described above is used to estimate carbon sequestration impacts from LULC change across the watershed. Finally, the annual net return to marketable good production (conventional crops or pasture, switchgrass, prairie grass, and timber and pulp) across the landscape is calculated using crop and other plant yields as predicted by SWAT in conjunction with data on the observed prices and costs of producing conventional crops and timber and the expected prices and costs associated with switchgrass and prairie crop production ([Pennington et al., in preparation](#)).

In [Figure 1](#) we indicate how much more additional P can be retained each year by the landscape compared to the current LULC and land management pattern where each point on a frontier represents a different LULC and land management pattern. There are multiple solutions (LULC and land management patterns) because we vary the minimum allowable change in annual net return to marketed goods and gain in carbon storage produced across the watershed. For example, point A represents the LULC pattern that maximizes P retention *given* the annual net return to marketed goods produced across the landscape has to increase by at least \$50,000 compared to the baseline (the current landscape) and steady-state carbon storage levels has to increase by at least 1000 Mg compared to the baseline (at point A changes on the landscape are expected to increase annual P retention by 524 kg). Point B represents the LULC and land management pattern that maximizes change in P retention *given* the annual net return to marketed goods produced across the landscape cannot fall more than \$3.5 million per year and steady-state carbon storage levels has to increase by at least 25,000 Mg (at this point changes on the landscape are expected to increase annual P retention by 2074 kg). The next step in this analysis would be to determine how valuable the extent of modeled P retention and increased carbon storage is to people on the landscape

Figure 1 Each point along a frontier gives the maximum gain in annual P retention possible in the Seven Mile Creek watershed compared to baseline retention when gains are constrained by a minimum marketed good value and carbon sequestration production in the watershed. Annual retention of P is increased by changing the LULC and land management pattern in the watershed. Increases in annual retention are constrained by limits on how much of the watershed's annual net return to marketed goods can change (x-axis) and minimal necessary gains in steady-state carbon storage on the landscape. The required gain in metric tons of carbon is indicated by the number at the terminus of a frontier. Baseline output of P retention, carbon storage, and annual return to marketed goods is represented by the origin of the graph. Point A represents the LULC pattern that maximizes P retention given the annual net return to marketed goods produced across the landscape has to increase by at least \$50,000 and steady-state carbon storage levels has to increase by at least 1000 Mg compared to the baseline. Point B represents the LULC pattern that maximizes change in P retention given the annual net return to marketed goods produced across the landscape cannot fall more than \$3.5 million per year and steady-state carbon storage levels have to increase by at least 25,000 Mg.

and in the case of carbon sequestration, to the people across the globe.

Figure 1 highlights several important points about ecosystem service provision that is useful to communicate to policy makers. First, the more society is willing to sacrifice in marketed net returns and, in some cases, the provision of other services, the more we can gain in a targeted service (in this case, P retention). Second, in this case and as noted in other research (e.g., Polasky *et al.*, 2011), current LULC patterns tend to be inefficient, both from an ecosystem service and marketed returns perspective. In this case the provision of both ecosystem services and marketed net returns could be improved, for example, Point A in **Figure 1**, with smarter land use planning or targeted land use incentive programs.

Market inefficiency is contrary to the fundamental economic assumption that land is always put into its best economic use. These modeled market inefficiencies in **Figure 1** could be due to model limitations (e.g., the costs of LULC transition, not accounted for in our model, are significant, the price and production data we used are erroneous, the modeled yield from SWAT is erroneous) or they could be real (e.g., landowners are choosing not to maximize net returns for some nonmarket-related reason, landowners are unaware of their best options, etc.).

Software That Supports Ecosystem Service Modeling

Up to this point in time, most published ecological process models have focused on one or a collection of closely

related services (including the models noted above such as CENTURY, EPIC, SPARROW, etc.). However, there are several inchoate efforts to apply consistent modeling approaches and algorithms across a suite of services (Waage *et al.*, 2011). Artificial Intelligence for Ecosystem Services (ARIES) is one such tool. ARIES first collects information on the user's analysis objective. Next, the user can access data on their landscape of interest from a GeoServer or submit their own maps of the landscape's LULC and biophysical conditions (Villa *et al.*, 2009). ARIES then maps the topology and strength of ecosystem service flow across the landscape for those services that are relevant to the user's analysis objective (Johnson *et al.*, 2010). Flow maps are overlaid with maps of human presence on the landscape to determine the extent to which humans benefit from ecosystem service provision or flow. Default ARIES results are based on observed patterns of service flow on other landscapes that have very similar conditions to the landscape of interest; however, biophysical models can be used to modify these default results as long as the user supplies the necessary information and data (Vigerstol and Aukema, 2011). Service benefits in ARIES can be monetized with a benefits transfer approach or with market, avoided, and replacement valuation techniques discussed above.

Integrated Valuation of Ecosystem Services and Trade-offs (InVEST) is a suite of service models that use production functions to convert maps of LULC, land management, and biophysical conditions into maps of service supply (Tallis *et al.*, 2011). In addition, InVEST models determine the extent to which the supply of services is useful or valuable to people on the landscape. The storm peak mitigation, nutrient retention, and pollination models described above are part of

InVEST. Because data needed to run more complicated service models are often scarce, the current version of InVEST offers relatively simple models with fewer input requirements. The simplicity of the first tier of InVEST models means that results should be viewed with some skepticism. As of now the InVEST is an add-on to ESRI's ArcGIS software. The development team behind InVEST, in cooperation with Google, plans to incorporate several InVEST models into Google's Earth Engine for use with Google Earth. Further, there are plans to publish more complex models and to make InVEST models much more accessible to the open source community.

ENVISION is a GIS-based software system that creates future LULC patterns on a landscape as a function of user-defined economic and environmental policies. The impact of the generated landscape on ecosystem service provision and value can be estimated within ENVISION by accessing any of the ecosystem service models that have been linked to ENVISION.

Other ecosystem service modeling and assessment projects include Ecological Asset Inventory and Management (EcoAIM), EcoMetrix, Ecosystem Services Review (ESR), ESValue, and Natural Assets Information System (NAIS) (Waage *et al.*, 2011).

Using Terrestrial Ecosystem Service Modeling to Affect Decision Making

Ideally, ecosystem service models and analyses will increasingly be used to inform policy-maker decision making and suggest land use policies, regulations, and payment for ecosystem service mechanisms that lead to a net increase in the societal benefits generated on a landscape. As an example of this process, the Sumatra Spatial Planning Forum, a coalition of Indonesian academics and nongovernmental organizations, has been using InVEST to make LULC pattern recommendations that would bolster biodiversity and ecosystem service conservation on the Indonesian island but still provide opportunities for robust economic development. Sumatra's forests have declined in area by a quarter between 2000 and 2010 (Miettinen *et al.*, 2011). Besides reducing the provision of the global public goods of biodiversity conservation and carbon storage, deforestation on Sumatra also degrades the island's water quality and reduces locals' access to valuable forest products.

InVEST has been used to map the distribution of terrestrial carbon stock, water yield, sediment retention, water pollution regulation, and wildlife habitat quality in central Sumatra as of 2008, and under two alternative future LULC scenarios: the Forum's "green vision" of sustainable land use, and the government's land use plan, which corresponds to a business as usual scenario (Barano *et al.*, 2010). These maps are being used to identify areas where conservation-friendly land uses and management practices could maintain or even enhance ecosystem service provision and wildlife habitat at lowest cost where conservation costs are represented by foregone forest plantation and agricultural net returns. The highest priority districts for investment in forest carbon conservation according to the Forum's analysis are those where forest carbon stocks were high as of 2008, the risk of deforestation is high, and monetary returns from foregone plantations and

agriculture are low. Similarly, the Forum has identified watersheds where programs to reduce sediment and nutrient pollution could benefit downstream users.

The advice that the Forum is giving the Indonesian government could be improved in several ways. The analysis in Sumatra has been conducted with InVEST's simpler models and coarse global datasets. It is not known how much the targeting maps would change with finer-scale data and more complex models. Some important services, including non-timber forest products and ecotourism, both of which are potentially important for local livelihoods, have yet to be assessed. Further, the rapid rate of deforestation in Sumatra means that targeting maps produced by the Forum may be out of date soon after they are made. Therefore, targeting maps will need to be regularly updated if they are to remain relevant.

In other examples, InVEST has been used to inform a Kamehameha Schools' land use plan (the Kamehameha Schools is the largest private landowner in Hawai'i). The plan was given a 2011 National Planning Excellence Award for Innovation in Sustaining Places by the American Planning Association. InVEST is also being used across Latin America to inform water funds, through which downstream consumers pay upstream land managers for changes in practices to improve water supply. InVEST is used to inform fund size and targeting of payments, in terms of where they are made and the practices they support, in over 30 funds serving major cities. At the largest scale, InVEST is being used in China in a new policy that will designate 25% of the country as "ecosystem function conservation area" status. This policy has twin goals of securing vital natural capital (for flood control, sand storm control, water supply for irrigation and hydropower, and biodiversity) and promoting rural development to alleviate poverty. Decision makers are using InVEST to define the boundaries of the reserves and to evaluate more sustainable livelihoods that could be supported within them.

The Valuing the Arc project, based in Cambridge, UK, is using InVEST models and other modeling techniques and systems to estimate current and future ecosystem service provision and value across the Eastern Arcs Mountain range in Tanzania. The project's goal is to gain a better understanding of the ecosystem services provided by the Mountains and how they contribute to human welfare, and to find solutions to managing these services in a sustainable way. The project hopes to assist policy makers in Tanzania in their efforts to increase their people's welfare.

ARIES has been applied to landscapes in Western Washington, USA; Orange County, CA, USA; San Pedro River, AZ, USA; Vermont, USA; Dominican Republic; Veracruz, Mexico; and Madagascar.

Though the authors have not discussed the approach here in any detail, the benefits transfer approach to creating service value maps has been used to influence policy on several landscapes, including the US state of New Jersey (Liu *et al.*, 2010).

Conclusions

Land use and land management decisions have significant impacts on ecosystems and the goods and services they

provide. By modeling terrestrial ecosystem services we begin to understand the full range of valuable trade-offs associated with land use and land management change, not just those goods and services that are valued by markets. Here we have introduced methods and approaches to estimate how the provision and value of ecosystem services is affected by changes in land use, land management, and ecosystem conditions and human preferences and values on the landscape.

Ecosystem service modeling efforts in the future will need to do a better job of integrating all the spatial and temporal dynamics in service provision and its value. For example, consider the actions of a Minnesota farmer. As described in the detailed model discussion above, her decision to increase the nitrogen fertilization rate on her cropland increases the marketed value of goods produced on her land and may increase the productive value of services that support agriculture but has a detrimental effect on local water quality as nutrient runoff increases. However, if we do not consider the effect of this additional nutrient runoff even further downstream and eventually in the Gulf of Mexico, we have not fully evaluated the impacts of her decision. Further, the timing of impacts (e.g., how long does it take runoff from Minnesota to reach the Gulf) can impact ecosystem service values. Better terrestrial ecosystem service models will consider these complex spatial and temporal dynamics. In addition, the better models will be formally linked to marine ecosystem service models.

Still in its relative infancy, efforts to model trade-offs will become more accurate in the future as we improve our understanding of ecological processes and technical modeling capabilities advance. To improve our understanding of the ecological production functions, more empirical studies designed through an ecosystem service lens are needed to explicitly test the effects of multiple land use and management conditions on ecosystem structure and function. Ideally, such studies would be replicated across multiple ecosystems and biomes to account for spatial or temporal differences. However, no matter how sophisticated our models become, there will be many ecosystem dynamics that will prove difficult or impossible to quantify with certainty, such as threshold responses from changes in global climate. Therefore, responsible ecosystem service modeling will include sensitivity analyses to account for the uncertainty inherent to all modeling efforts.

Glossary

Bioassay A test for pharmaceutical activity in substances conducted either in living organisms (*in vivo* assays) or in the test tube (*in vitro* assays).

Coevolution A heritable response made by a species through evolutionary time to a different species that is then reciprocated.

Ethnobotany The study of the uses of plants by different groups of peoples, often indigenous peoples.

Extremophile An organism that lives and thrives in a habitat characterized by extremes of temperature, acidity, alkalinity, salinity, light, or pressure that would prove lethal to most other organisms.

Fractionation A method of obtaining a pure compound by extracting components of a mixture with solvents of different polarity.

Herbal A compilation of medicinal plants and their properties often used in earlier times as a reference for physicians prescribing medical treatments based on plant therapies.

Indigenous intellectual property rights Rights to intellectual properties belonging to indigenous peoples, including but not limited to iconographical representations, terminologies, names, phrases, legends, methods, and techniques of traditional cultivation, healing, identification, preparation, and other use of biodiversity.

Indigenous peoples Peoples who have resided in the same geographical area for many generations and who possess legends, proverbs, genealogies, languages, and other unique cultural features linking them to the land.

Shotgun DNA A technique that isolates deoxyribonucleic acid (DNA) fragments from soil or water samples and compares them to known DNA libraries to determine the presence of novel species.

Voucher A representative specimen of a plant or an animal that is properly collected, prepared, and preserved in a herbarium or museum to facilitate expert identification of the species.

Introduction

Pharmacology, the science of drugs, studies the ways in which natural products can be employed as medicines. Since ancient times, humans have recognized the pharmaceutical properties of certain compounds derived from plants and animals. Current research now also recognizes that biodiversity must be maintained in order for the environment to continue to be a source of such medicinal substances.

Evolutionary Perspectives

In the 4.5 billion years since the Earth was formed, living organisms have evolved a plethora of complex molecules to help mediate interactions with their physical and biotic environments. Approximately 3.6 billion years ago, organisms originated that use deoxyribonucleic acid (DNA) to transmit genetic information. However, it is believed that before the rise of DNA-based organisms, perhaps as early as 3.8 billion years ago, Earth was inhabited by organisms that solely used ribonucleic acid (RNA) as their primary genetic material (Joyce, 2002). Echoes of this previous RNA world can be found in ribosomal RNA (rRNA), which facilitates protein assembly. Even earlier, perhaps 4 billion years ago, before the rise of the RNA world, there was an era of self-replicating peptide nucleic acids (PNA), such as *N*-(2-aminoethyl)glycine units with the bases attached, bridging the abiotic and biotic eras. The interplay between increasing molecular diversity and the concomitant increase in biodiversity, which characterizes

the history of life on Earth, has resulted in an astonishing array of complex molecules, many of which cannot be synthesized in modern laboratories. This molecular cornucopia can be used to develop new drugs and new approaches to the treatment of disease, drawing from molecules that are themselves of ancient date. For example, the use of antisense RNA, RNA interference, or even antisense PNA, for novel antibiotics and gene silencing, has been informed by studies of “primitive” prokaryotes. And the relatively recent discovery of an entire new domain of life – the Archaea – which were initially believed to be limited to extreme habitats, but are now known to be relatively ubiquitous throughout Earth, has opened new approaches for drug discovery.

The evolutionary divergence approximately 3.5 billion years ago of the three major domains of life, the Eukarya, the Bacteria, and the Archaea, led to dramatic differences in species and molecular diversity among these domains. The International Union for Conservation of Nature (IUCN) estimates that there are 1.7 million known species of Eukarya, which include plants, animals, fungi, and algae. With an estimated 5.5 million eukaryotes remaining to be described, there are perhaps 5–15 million species of eukaryotes on Earth. This diversity, however, pales when compared to that of the prokaryotes. Based on shotgun DNA techniques, estimates of the number of species of bacteria have increased in the past three decades from several thousand to as many as a billion. Understandings of species diversity of Archaea, while nascent, are also increasing. Recently, the smallest known prokaryotes, with diameters as small as 500 nm, were discovered in acidic mine tailings in northern California by UC Berkeley researcher

Brett Baker (Baker *et al.*, 2010). An analysis of the Archaeum *Pyrococcus furiosus* by the biotech company Strategene led to the discovery of the enzyme Pfu DNA polymerase, which is useful in DNA fingerprinting and genetic engineering.

The inescapable conclusion of these considerations is that our planet is biochemically diverse and, as far as it is known, the most molecularly complex assemblage in the universe. Evolution has driven organisms to increasingly sophisticated levels of chemical interaction, with some of the resultant molecules functioning as materials for membranes and cell walls, quorum signals, photosynthetic pigments, energy storage compounds, neurotransmitters (in animals) and hormonal signals (in plants as well as in animals), defensive compounds, a variety of protective pigments, and structural materials. The resultant juxtaposition of similarity and diversity of the chemical compounds created by different life forms is striking. The ancient evolutionary divergences resulted in differential vulnerability to toxic compounds, with ranges in LD50s of specific compounds varying several orders of magnitude between different phylogenetic groups. For example, the concentration of penicillin that completely stops cell wall formation and growth in *Streptococcus* bacteria shows little effect when administered to a centipede or to a geranium, whereas the dose of 2,4-D sufficient to kill a geranium would have negligible impact on either centipedes or bacteria.

Throughout the history of life on Earth, such differences in biochemical vulnerability have generated abundant possibilities for chemical coevolution between different species. Even though life on Earth appears to share a common phylogeny, biochemical differences between species leave open the possibility that a mutation in the biosynthetic pathway of one organism may yield a compound toxic to another. Selection for such protective molecules from predation is perhaps the greatest in organisms that are unable to flee or lack alternative forms of defense. Among eukaryotes, sessile organisms such as corals, sponges, tunicates, and other marine invertebrates and most plants have been particularly rich sources of pharmaceuticals. Although poisonous birds have been found in New Guinea, toxic frogs are prominent in the Neotropics, and brightly colored toxic insects are known to most amateur naturalists, biochemical protection against predation appears to be the exception rather than the rule for motile organisms.

A plant species under pressure from a predator or parasite may perish unless individuals in the plant population possess, by mutation or some other evolutionary accident, a compound toxic or unpalatable to its enemies. If the mutation is heritable, progeny of such plants will increase in time throughout the population, replacing those individuals previously lost to predation. If the species of predator or parasite are highly selective in their choice of prey, they may in turn become imperiled by such chemical innovations, unless individuals in the predator or parasite population possess a means of detoxifying the defensive chemistry generated by the plants. The resultant coevolutionary race between two species, sometimes termed a "red queen race" after the never-ending contest described by Lewis Carroll in *Alice in Wonderland*, has been documented in the interaction between *Passiflora* vines and *Heliconius* butterflies in the Neotropics by Larry Gilbert and coworkers at the University of Texas. Other such tight coevolutionary links are the topic of much scientific interest.

More common than species-species coevolution is what might be termed diffuse chemical coevolution. Instead of evolving defensive chemistry against a single species of predator or parasite, a plant species generates compounds effective against a wide variety of plant enemies. The presence of toxic compounds in a plant cannot, however, be considered *prima facie* evidence of an evolutionary response to predation. Bioactive molecules occur in plants as secondary metabolites as well as evolved chemical defenses against predation, fungal attack, microbial invasion, and viral infection. It is also unlikely that plant compounds known to be toxic to humans represent evolutionary responses to anthropogenic harvesting; given the omnivorous, generalist foraging patterns of higher primates, it is unlikely (with the possible exception of agricultural weeds) that, absent artificial selection, any plants have evolved a specific biochemical response to consumption by humans. However, hundreds of thousands – perhaps even millions – of bioactive molecules in nature result from plant chemical warfare with viruses, bacteria, fungi, and animals. Many of these compounds, although toxic at certain doses, can be beneficial to humans at lower doses.

The emerging picture of chemical interactions between sessile prey and motile predators is compelling. What might otherwise appear to be a quiet forest glen or a tranquil coral reef may be the evolutionary equivalent of a battlefield rife with chemical warfare. Sessile prey appear to sequester toxic agents, and motile predators develop detoxification strategies at a prodigious rate through evolutionary time. Since many of these bioactive molecules have relevancy to human disease, a coral reef or forest glen could also be said to resemble a large pharmaceutical storehouse, perhaps one that is in great disarray. Tens of thousands of vials of pharmacologically active compounds litter the factory floor, but the labels identifying the contents and their therapeutic utility have been lost. How can one determine which molecules are useful and for which diseases?

Eloy Rodriguez and coworkers at Cornell University have found evidence that some vertebrates self-dose with pharmacologically active compounds produced by plants. Many mammals, including primates, engage in self-medication when ill. Ongoing pharmacological self-experimentation by animals may have been observed and mimicked by early humans. Polynesian legends indicate that kava, a beverage made from the roots and rhizomes of *Piper methysticum* rich in tranquilizing sesquiterpenes and kava lactones, was discovered by watching the calming effect the roots had on rats. Legends from India claim that in ancient times, mongooses were observed to feed on *Rauvolfia serpentina* before engaging in combat with cobras. Copying the reputed feeding behavior of the mongoose, local people found that the shrub could serve as a potent antidote to snakebite. The veracity of such legends is unclear, but it seems useful to trace the use of plant-derived bioactive molecules in medicine whose use in prehistory by indigenous peoples must first be examined.

As powerful as the paradigm of competition was for pioneers in the theory of evolution, more recent focus has been directed toward evolutionary cooperation. Mutualisms and symbioses may prove to be much more common than had previously been suspected, particularly when beneficial evolutionary relationships between prokaryotes and eukaryotes

are considered. For example, both termites and cattle depend on the presence of methanogenic archaea in their guts to digest cellulose. Endophytic cyanobacteria in the roots of cycad trees produce a potent motor neuron toxin, β -N-methylamino-L-alanine (BMAA), which once likely served to protect the ancestors of modern cycads from dinosaur herbivory. And the emerging study of biofilms has profound implications for human health ranging from new antibiotics to strategies for implantation of artificial organs. The molecular signaling involved in the establishment and maintenance of symbioses and biofilms represents a new and largely untapped frontier for pharmacology. Already disruption of quorum sensing molecules has been used to target biofilms characteristic of chronic human infections (Hentzer *et al*, 2003).

History

Early Understandings

All known indigenous peoples have ethnomedical traditions based, at least in part, on pharmacologically active compounds found in plants and animals. It is therefore safe to assume that early humans also developed significant ethnopharmacopoeias; this assumption is corroborated by archaeological findings of what appear to be medicine pouches in ancient burial sites. Results of successful experiments with pharmacologically active plants and animals were likely passed from generation to generation. This accumulation of oral information resembles in part the results of a vast, uncontrolled, and unwritten human bioassay experiment. Later knowledge about medicinal plants was transmitted in written form. By the fifth century BC, Hippocrates codified and disseminated knowledge from earlier times concerning plant medicine in the Mediterranean area. During this period, commerce in medicinal plants was vigorous, especially with traders called *rhizotomii* dealing principally in plant roots. The folk knowledge accumulated by the *rhizotomii* was subsequently studied by scholars, including Aristotle (384–322 BC), who laid a foundation for the philosophical consideration of plants. Aristotle bequeathed his library to his student, Theophrastus, who wrote the most important book on plants up to that time, *De Causis Plantarum*, and who is now regarded to have been the first academic botanist. In his *Inquiry into Plants*, which in the ninth book catalogs information on medicinal plants, Theophrastus incorporated information from the *rhizotomii*. He was, however, skeptical of folk superstitions concerning the gathering of medicinal plants.

In the first century, Pedanius Dioscorides, a Greek physician, wrote a seminal work on medicinal plants titled *De Materia Medica*, which describes more than 500 medicinal plants and includes many drawings. Until the beginning of the Renaissance, Dioscorides's work was the final word in medicinal plants for more than 1000 years.

Such early compilations of folk wisdom concerning medicinal plants were not confined to the West. In 2000 BC, the Chinese emperor Chi'en Nung compiled the *Pen Tsao*, which is perhaps the earliest known herbal. In India, Sanskrit texts on medicinal plants date to 3000 years ago. In the

Americas, the Mayans also wrote extensive manuscripts on medicinal plants. Unfortunately, many of these codices were burned by the early Spanish conquistadors who took such examples of scholarly achievement by their unchurched and "uncivilized" indigenous opponents as evidence of demonic influence.

Herbals and Medicinal Plants

In Europe, an increase in scholarly interest in herbals and medicinal plants began during the Renaissance, when the first physic gardens (gardens of medicinal plants for therapeutic use and study) were planted in Italy and Germany. Most early Renaissance herbals were largely based on the work of Dioscorides's book, *De Materia Medica*, with additions made from the author's own knowledge. As can be seen in *De Materia Medica*, two pieces of information were disseminated concerning each plant: its purported healing properties and its identification.

Arber (1953) pointed out that the necessity for precise identification led to an unusual feature of early botanical iconography: For nearly 2000 years, plants in herbals were pictured with the part most likely to be in commerce: their roots. Although these earlier herbals were lovingly copied throughout the ages, the quality of illustrations declined until, in the fourteenth century, it had become increasingly difficult to identify the plants. Innovators such as Fuchs and Mattioli began to inscribe illustrations drawn from living plants on wood blocks for printing. This was a major boon for botanists since images reproduced by wood block printing did not suffer the same image deterioration in successive copies as occurred in hand-inked illustrations. The new herbals also contained current information gleaned from European folk medicine.

In the English-speaking world, the first herbal is an eleventh-century Anglo-Saxon codex known as the *Herbarium of Apuleius Platonius*. The earliest printed English herbal is an anonymous quarto from 1525 imprinted by Richard Banckes (as quoted in Arber, 1953, p. 41): "Here beynneth a newe mater, the whiche sheweth and treateth of y vertues and propertes of herbes, the whiche is called an Herball."

A year later, a translation of a French herbal was published by Peter Treversi, and in 1538 William Turner published *Lebellus de re Herbaria Nova*. In 1551, Henry F. Lyte published a translation of Dodoen's famous herbal, and in 1555 Anthony Askham published a herbal derived from the 1525 English work of Banckes. However, the most popular of all sixteenth-century herbals was that of John Gerard, published in 1597.

Born in 1545, at the age of 32 Gerard was appointed superintendent of the gardens of Lord Burleigh at the Strand in London. Later, he was appointed as the curator of the Physic Garden of the College of Physicians of London. A catalog of plants in his own garden appeared in 1596, and in 1597 he published *The Herball, or General Natural History of Plants*, one of the most quoted botanical works ever published. The only published text to have remained constantly in print for such a long period is the Bible. Gerard's *Herball*, with 1392 pages and 2200 woodcut images of medicinal plants, was greeted with tremendous enthusiasm by medical practitioners and the general public.

The importance of Gerard's *Herball* in the history of discovery of novel bioactive compounds from biodiversity cannot be overstated. His description of the medicinal properties of *Filipendula* – now called *Spirea* – a genus in the rose family, led to the isolation of salicin and the eventual synthesis of "A *Spirea* n" or aspirin. Another example is Gerard's entry on page 646 "of Foxe gloves":

Foxe gloue boiled in water or wine, and drunken, doth cut and consume the thick toughnes of grosse and slimie flegme and naughtie humors; it openeth also the stopping of the liver, spleene and milt of other inward parts.

Gerard's recording of foxglove opening the stopping of "other inward parts" was not systematically examined for 200 years. In 1785, William Withering published *An Account of the Foxglove and Some of Its Medical Uses: With Practical Remarks on Dropsy and Other Diseases*, in which he quoted Gerard's account of the "vertues" of foxglove and proposed that foxglove could be an important medicine for dropsy, an ailment caused by the retention of fluid due to inadequate pumping action by the heart. The connection between dropsy and heart disease was not properly understood in Withering's day, but Withering observed the action of foxglove on the heart: "It has a power over the motion of the heart, to a degree yet unobserved in any other medicine, and ... this power may be converted to salutary ends." By any standard, foxglove as administered by Withering was an astonishingly successful treatment for dropsy. J. K. Aronson at Oxford recently reanalyzed data from Withering's cases and found a cure rate of between 65% and 80%.

The Linnaean name given for foxglove, *Digitalis*, was affixed to the crude drug as well as to cardiac glycosides (steroidal compounds with sugars attached at the 3-position) isolated from foxglove in the early twentieth century. More than 30 cardiac glycosides have been isolated from dried foxglove leaves, including digitoxin and digoxin. These two drugs have never been synthesized, and they are still extracted from dried foxglove leaves. Each year, more than 1500 kg of pure digoxin and 200 kg of digitoxin are prescribed to thousands of heart patients.

Digitalis, however, is but one drug inspired by Gerard's *Herball*. Since the publication of the *Herball*, 18 different pharmaceutical compounds have been isolated from plants that Gerard described, including 16 drugs prescribed today. It is likely that the English translation of *Herbarium Amboinense* by Rumphius will also lead to the discovery of new drugs from an ancient text as will analyses of other historical herbals (Buenz *et al.*, 2004).

European herbals and folk medicine were not the only source of pharmaceuticals; drug discovery has been greatly enhanced by non-Western traditions such as Ayurvedic medicine in India. For example, *Rauvolfia serpentina* has long been used in India to treat snakebite and insomnia and as a sedative for hyperactive children. In 1931, Indian chemists isolated a variety of molecules from the plant and later found that *Rauvolfia* powder lowered blood pressure. In 1949, R. J. Vakil published a clinical study of *Rauvolfia* in the *British Heart Journal*. Following up on Vakil's research, Dr. Emil Schlittler and Hans Schwarz at CIBA extracted from *Rauvolfia* roots an

alkaloid, reserpine, which at low doses shows strong activity in lowering blood pressure. CIBA soon introduced reserpine to commerce. Reserpine had a direct effect on the hypothalamus and recently has been prescribed in combination with other antihypertensive drugs such as hydralazine hydrochloride.

Modern Chemical Approaches to Drug Discovery

Digitalis was discovered through the same sequence of steps used in modern ethnobotanical drug discovery programs: (1) folk knowledge accumulates concerning possible pharmacological activity of a plant, (2) the plant is used therapeutically by a healer, (3) the healer communicates this knowledge to a scientist, (4) the scientist collects and identifies the plant, (5) plant extracts are tested with a bioassay (a preliminary screen for desired pharmacological activity), (6) a pure compound is isolated using the bioassay to trace the source of the activity in the plant extract, and (7) the structure of the pure substance is determined.

This method of discovery and isolation of new drugs from plants persisted until the 1950s because most pharmaceutical research relied heavily on compounds derived from vascular plants, particularly plants used in folk medicine. Indeed, flowering plants and ferns (as opposed to microscopic organisms and fungi) have given rise to approximately 120 commercially sold drugs. Of the top 150 prescription drugs in the US, 57% contain at least one compound derived from biodiversity, including plants, animals, fungi, and bacteria (Grifo and Rosenthal, 1997). One-fourth of all US prescription drugs contain molecules derived from, or modeled after, naturally occurring molecules in higher plants (Grifo and Rosenthal, 1997), including reserpine, digitalis, vincristine, and many other compounds derived from plants used in traditional medicine.

The importance of biodiversity-derived drugs is particularly evident in cancer therapy. From 1981 to 2002, 62% of novel molecular entities showing anticancer activity were non-synthetic. And of 74 synthetic drug candidates developed during the same time frame, 48 mimic natural products (Newman *et al.*, 2003; Newman and Cragg, 2007).

In the late 1950s and early 1960s, the search for bioactive molecules expanded to the marine environment. Increased access to underwater breathing apparatus and small submersible craft made studies of novel bioactive chemicals produced by marine organisms far easier. In the underwater realm, most discoveries of novel bioactive molecules had no basis in folk knowledge, even though evolutionary processes similar to those that produced large chemical diversity in higher plants are also believed to be operant in the marine environment, particularly among sessile organisms such as corals, sponges, and tunicates. It is somewhat surprising that few indigenous cultures rely on marine organisms as part of their pharmacopoeias, but perhaps difficulties in harvesting marine resources in the absence of SCUBA technology and the unpredictability of capturing mobile marine organisms resulted in greater indigenous reliance on terrestrial plants.

Natural products derived from biodiversity may contribute to the search for new drugs in three ways: (1) by producing new drugs used in an unmodified state (e.g., vincristine from

Catharanthus roseus (Apocynaceae)), (2) by providing chemical "building blocks" used to synthesize more complex compounds (e.g., the synthesis of oral contraceptives from diosgenin derived from *Dioscorea composita* and *Dioscorea mexicana* (Dioscoreaceae)), and (3) by indicating new modes of pharmacological action that allow complete synthesis of novel analogs (e.g., synthetic analogs of reserpine from *Rauvolfia serpentina* (Apocynaceae)).

Regardless of their origin, recent discoveries of potential new pharmaceuticals have been facilitated by increasingly sophisticated techniques of vouchering and species identification, bioassay, fractionation, and structural elucidation of molecular entities.

Vouchering

Proper vouchering in pharmaceutical research has sometimes been overlooked with disastrous effects because accurate identification of a species of plant or marine organism has been rendered impossible due to a missing or inadequate voucher specimen. The importance of adequate herbarium voucher specimens cannot be overstated: Any subsequent question or dispute concerning the identity of the species involved can be unequivocally settled by expert examination of a properly collected voucher specimen. Vouchers for fish and marine invertebrates are usually stored as dried or fluid preserved (FAA or aqueous ethanol) specimens deposited in zoological or natural history museums. Specimens of algae, lichen, and vascular plants are preserved as dried specimens in herbaria. Because of their scientific value for the future (sophisticated bioassays of the future may require only micrograms of material), voucher specimens should be deposited and preserved in well-curated herbaria or museums with duplicate specimens deposited in geographically distant institutions, including institutions in the countries in which the material was collected. Addresses and contact information for herbaria throughout the world are listed in *Index Herbariorum*, published by the International Society of Plant Taxonomists and the New York Botanical Garden.

The collection number of the specimen should be used to label all subsequent pharmacological fractions and residues so that any new discovery or question can be immediately referred to the original specimen. Herbarium specimens should consist of the leaf, fruit, flower, and other plant parts necessary for proper identification by a botanist. Plants are pressed in newspaper and dried in the field using plant presses and a heater. When it arrives at the herbarium, the dried plant material is glued to high-quality rag bond paper and stored in files in herbarium cases. Properly stored under the correct conditions, herbarium specimens can retain their scientific value for centuries. In the field, it is also important to take careful notes to accompany the voucher specimens, including precise information on the collection location and other information on the plant, such as floral odor or color, that might be lost during drying. The collector's name and date of collection should always be included. For plants or animals used in folk medicine, ethnobiological data on the diseases treated, mode of formulation, and methods of administration should be sufficiently detailed to guide subsequent investigations.

In preparing samples for pharmaceutical testing, drying is used to stop enzymatic processes of degradation: Most cease when water content is reduced to 10% by volume. Rapid drying is preferred, although high temperatures can alter pharmaceutical constituents. Air drying at 20–40 °C is preferred, but sometimes in the moist tropics, temperatures must be raised far higher to promote drying of bark or roots. With access to the laboratory, freeze-drying of a sample is an attractive alternative, whereas under field conditions in the humid tropics, fluid preservation in aqueous ethanol or formalin is often necessary to prevent spoilage of the sample.

The vouchering of prokaryotic samples is more difficult, particularly given the rise of shotgun DNA techniques that can identify new species of archaea and bacteria in the absence of the entire organism. In shotgun DNA techniques, pioneered by Craig Venter and his colleagues, DNA from soil or water is split into small random fragments. These fragments are attached to viral DNA and packaged to create DNA libraries. The resultant DNA libraries are sequenced, with overlapping DNA sequences assembled by computer. Each full DNA sequence is then compared to known DNA sequences, and novel DNA sequences are placed in the database as evidence of a new species.

The increase in species discovery using shotgun DNA techniques is phenomenal, with individual scientists being able to collect up to 100 new species per day. While the establishment of an axenic culture deposited with either the American Type Culture Collection (ATCC) or the Pasteur Culture Collection (PCC) remains the gold standard of prokaryotic vouchering, difficulties in culturing, let alone describing new bacteria or archaea identified through shotgun DNA techniques, suggest that vouchering in the future may revolve around publicly accessible databases for DNA sequences.

Bioassays

Bioassays vary with regard to type and precision. *In vivo* bioassays involve administering the test substance to a living organism to determine the substance's pharmacological activity. One of the more common *in vivo* bioassays that has been used to great advantage by some investigators is a brine shrimp bioassay, in which the test substance is administered to a culture of brine shrimp, available from any aquarium supplier. The percentage death of the brine shrimp within a short period is recorded, with brine shrimp mortality yielding a crude measure of cytotoxicity. Other *in vivo* bioassays include the Hippocratic screen, a test protocol for oral or peritoneal administration of the test substance in rats or mice. Various behavioral and physiological parameters are measured before and after administration, allowing the type and mode of pharmacological activity to be adduced. The most important *in vivo* bioassays for pharmaceutical research are human clinical trials, which are almost always administered after reasonable expectations of safety and efficacy have been determined from animal trials. The power of *in vivo* assays is their ability to reveal unexpected or novel modes of pharmacological activity since the impact of the test substance on the whole organism can be studied.

More common in modern pharmaceutical use, though, are *in vitro* assays – bioassays that do not depend on a living organism. Although some broad-based *in vitro* assays depend on living tissues or cells, such as the guinea pig ileum, frog sciatic nerve, or human cancer cell lines, far more common is the use of target-specific molecular assays. In such assays, a single point of action in a given biochemical pathway, such as the role of the enzyme phospholipase A2 in mediating cellular inflammation, has already been identified. Various substances are then screened to determine if they impact the enzyme, receptor, site, or rate-limiting step of interest. Modern high-throughput *in vitro* assays are typically costly (given the immense research effort required to identify the best target along a given biochemical pathway), proprietary, and designed for high-throughput rapid testing of numerous samples for the desired pharmacological activity.

In a typical high-throughput bioassay, minuscule portions of a given sample are tested for an enzymatic color change when combined with the test system. These bioassays test by screening, using a computer-controlled camera, hundreds and even thousands of different samples deposited in the micro-wells of a glass dish that are manipulated by robotic arms. The advantages of modern high-throughput bioassays are their speed, efficiency, repeatability, and specificity. The number of false positives (initial indications of pharmacological activity that do not pan out in subsequent testing) in modern receptor-binding assays is low; however, such high specificity entails a research liability since, unlike tests on living animals, a molecular bioassay is unlikely to reveal any mode of pharmacological action other than the specific activity it is designed to detect.

The use of precise high-throughput bioassays designed by molecular biologists has resulted in some spectacular successes, such as the discovery of the cholesterol-lowering drug Zocor or the generation of antiinflammatory drugs based on COX-2 inhibition such as Celebrex. However, such screens almost certainly miss many important modes of action. It is unlikely, for example, that the psychotropic action of LSD or the utility of phosphodiesterase inhibitors such as Viagra to treat male erectile dysfunction would have ever been discovered had their effects not been noted through inadvertent administration to living human beings.

Isolation

Once a “hit” or pharmacological activity is detected in a test substance during a bioassay, the substance, particularly if it is a natural product of unknown chemical composition, must undergo fractionation. During fractionation, solvents of different polarity are used to produce increasingly refined chemical samples of the test substance. Each fraction is then tested against the original bioassay to determine its bioactivity. Fractions exhibiting significant bioactivity are further fractionated until eventually a purified compound is obtained. High-pressure liquid chromatography, gel electrophoresis, and other chemical techniques are also employed in addition to solvent fractionation to purify samples. This approach to isolating pure bioactive molecules by tracing bioactivity

through the purification process is called bioassay-guided fractionation. Typical yields of pure bioactive molecules under research settings are low: Depending on the nature of the active molecule, 1 kg of dried plant material can yield as little as 1–10 µg of pure compound. Thus, on detection of a hit in a bioassay, recollection of a bulk sample (10–40 kg) is often required to produce sufficient pure substance for structural determination.

The advent of tandem mass spectroscopy with time-of-flight analysis coupled with computer-intensive pattern analysis has made the detection of small molecule metabolites much more accessible to investigators. By comparing genotypes with and without a known pharmacological activity, subtraction of all possible metabolites can result in identification of active molecules. However, as common to most emerging fields, many difficulties in both technique and analysis remain. Similarly, an analysis of the transcriptome, a set of all RNA molecules produced, can facilitate the analysis of genes and gene products involved in a disease. This in turn can be used as both a bioassay and an isolation technique for natural products that alter the transcriptome by modulating gene expression. Richard Weindruch and his colleagues in Madison, Wisconsin, are exploring how to achieve antiaging effects analogous to severe caloric restriction via changes to the transcriptome induced by natural products. They report that consumption of resveratrol, a molecule derived from red wine, mimics the gene expression of mice subjected to a severely calorie restricted diet (Barger *et al.*, 2008).

Structural Determination

Once a pure bioactive molecule is obtained through fractionation or chromatographic techniques, the next step is to determine its molecular structure. A definitive technique for determining the structure (if the purified molecule can be crystallized) is X-ray crystallography, but more common techniques involve the use of high-pressure liquid chromatography, gas chromatography (GC), mass spectrometry (MS), or, for novel structures, nuclear magnetic resonance (NMR) spectroscopy. Triple quadrupole mass spectrometry/mass spectrometry has been the most useful in detecting small molecules in complex matrices if purification is not possible (Domon and Aebersold, 2006). Most modern MS instruments have a computer-based library documenting molecular weights of known molecules; observed peaks are quickly and easily compared to those in the computer library. This technique is particularly useful for forensic toxicologists who do not typically expect to find novel molecules in their work. Structural determination in most biodiversity studies, however, relies on NMR since novel rather than known structures are often discovered during the course of pharmaceutical research. The frequencies and resolution capabilities of NMR machines differ, as do the types of experiments possible on NMR equipment, but of particular interest to natural product investigators is the INADEQUATE experiment, which, through supercomputer analysis, can resolve structures for molecules in substances that are parts of mixtures rather than pure samples. X-ray crystallography can resolve structures that are difficult to resolve through NMR.

Rational Screens of Biodiversity

Sometimes, such as in the case of penicillin, discovery of new pharmaceuticals from biodiversity is the result of serendipity. More often, though, success in natural product research is the result of carefully designed screening processes. Such planned search strategies to select appropriate organisms for study are termed “rational screens,” of which there are several varieties: random, phylogenetic, ecological, and ethnobotanical.

Random Screens

Random screens, despite their name, involve a great deal of planning and design. To be successful, they must have a clearly defined disease target and a clear and unambiguous bioassay. One of the best examples of a successful random screen in recent times is the effort of the Natural Product Branch of the U.S. National Cancer Institute (NCI) to evaluate plants and animals for anticancer activity. Using a variety of *in vitro* cancer cell cultures as bioassays, the NCI screened more than 35,000 plant accessions and 6000 marine organisms for activity against human cancers. Although the screen was not truly random in that it was designed to sample a wide range of geographical and taxonomic diversity, it allowed the NCI (with a variety of contracting collecting institutions) to assemble a large archive of materials that could be retested as bioassays continued to evolve. The geographical reach of the NCI was truly broad and led to pioneering efforts to negotiate international protocols for biodiversity prospecting. The NCI “letter of intent,” which collaborators used to obtain collecting permits in foreign countries, pledges equitable sharing of data and economic benefits with host countries. This letter has emerged as a model for recent international agreements.

Although the low hit rate of the NCI random screens led to criticism of the approach, few can argue with the stellar success of the NCI program in producing what may be one of the most important chemotherapeutic agents discovered in the latter part of the twentieth century, taxol, which was initially isolated from the Pacific yew tree (*Taxus brevifolia* (Taxaceae)) and which has been licensed by the NCI to Bristol Meyers and approved by the Food and Drug Administration (FDA) for the treatment of ovarian and breast cancers. However, because of the low success rates and high costs of collection, random screens are currently suitable only for large institutions, even given the advent of high-throughput bioassays.

Phylogenetic Screens

Phylogenetic screens involve the pharmacological testing of related groups of organisms. Increased precision in elucidating phylogenies, largely due to rapid computer programs for cladistic analysis and the advent of molecular techniques for phylogenetic determination, facilitates the identification of relatives of any species showing pharmacological value. Phylogenetic screens, albeit in a crude sense, have long been utilized. For example, plants in the Apocynaceae, or milkweed family, have always merited special attention due to the family's abundance of alkaloid-producing species such as *Catharanthus*, which produces the antileukemia drug

vincristine. Only recently have modern techniques encouraged investigators to study close relatives of a species for either (1) increased abundance of an important bioactive compound (such as species of *Taxus* for the presence of taxol) or (2) natural homologs of known pharmaceuticals (such as species of *Catharanthus* that may produce variant forms of vincristine or vinblastine).

Ecological Screens

An ecological screen depends on the environmental setting of the organism for clues as to its possible pharmaceutical value. Recently, such screens have focused on extremophiles – organisms that survive under extreme conditions of high temperatures, acidity, alkalinity, or salinity. For example, the polymerase chain reaction, invented by Kary Mullis at Cetus Corporation and widely used for genetic studies, medical diagnosis, or gene therapy, depends on an enzyme, Taq polymerase, a heat-stable DNA polymerase derived from a bacterium discovered in the thermal springs of Yellowstone National Park by Thomas Brock of the University of Wisconsin. The bacterium that produces the enzyme, *Thermus aquaticus*, can withstand temperatures of up to 95 °C, and its enzymes are similarly heat resistant, an important feature for the rapid thermal cycles used in the polymerase chain reaction.

Ecological screens have also been conducted underneath the sea near hydrothermal vents where temperatures can reach more than 350 °C. The enzyme Pfu DNA polymerase, derived from the Archaeum *Pyrrothus furiosus* and discovered by Karl Stetter of the University of Regensburg during exploration of undersea thermal vents, is of increasing interest because of its precision in polymerase chain reactions due to a built-in DNA repair mechanism. *P. furiosus* can survive temperatures more than 100 °C and is resistant to high pH and radioactivity. Enzymes derived from other organisms that survive conditions of extreme cold, alkalinity, acidity, or salinity are of increasing interest to the biotechnology industry (Madigan and Marrs, 1997).

Other ecological screens focus on searches for antifungal compounds from plants that grow in moist tropical environments (successes in this area have been achieved by Alice Clark at the University of Mississippi) as well as searches for inexpensive molluscicidal compounds useful in the fight against schistosomiasis. Kurt Hostettmann and his colleagues at the University of Lausanne discovered saponin-like compounds in several African tree species that show intense toxicity to schistosomiasis-carrying snails (Teryvaud *et al.*, 2000). They are investigating the possibility of supplying villagers with seeds and the simple techniques to prepare the crude solutions of these compounds, which could be used to dose village bathing and washing areas.

Ecological screens can also identify those few animals that produce useful pharmaceuticals. The Gila monster, a venomous lizard of the southwestern USA, produces venom in modified salivary glands resulting in severe pain and a drop in blood pressure in their prey. In 2005, a synthetic version of the protein exenatide derived from saliva was approved for treatment of type 2 diabetes. Marketed as Byetta, the drug regulates

glucose and causes decrease in appetite, leading to weight loss (DeFronzo *et al.*, 2005). Similarly, studies of toxins used by marine cone shells have led to the discovery of neuropeptides that show great potential in treating chronic pain (Olivera, 2006). The drug Prialt (generically called ziconitide) from the venom of *Conus majus* was approved in 2004 by the FDA for treatment of severe, chronic pain.

Ethnobotanical Screens

An ethnobotanical screen is based on the finding that indigenous peoples through generations have accumulated useful information about pharmaceutically active plants and animals (Cox, 2000a). Since ethnobotanical leads have resulted in the discovery of the active compounds for 25% of all prescription drugs, there is little question as to the efficacy of ethnobotanical approaches to drug discovery (Cox and Balick, 1994). However, although there are strengths to ethnobotanical screens, significant limitations also exist.

In general, cultures with three characteristics seem most likely to have discovered pharmacologically active plants: (1) residency within an area of high biodiversity, (2) an extended history of residence within the area, and (3) a cultural mechanism for accurate transmission of ethnomedical information from generation to generation. Under the first criterion, the Kayapo Indians of Brazil merit more attention than the Aleuts in Alaska because of the greater biodiversity of tropical Brazil. Under the second criterion, the aboriginal peoples of North Arnhem Land who have been resident in Australia for thousands of years would be of more interest than the Pitcairn islanders who arrived in their island home only a few centuries ago. Under the third criterion, the Samoan islanders, with a precise matrilineal system of transmitting healing knowledge from generation to generation, would be of more interest than faith healers in the Philippines, who depend on dreams for their knowledge of healing plants.

In an ethnobotanical screen, healing information is recorded by a linguistically adept ethnobotanist trained both in the techniques of ethnographic interviews and in field botany. Often, there is little overlap between indigenous and Western disease concepts. For example, there is no Western equivalent of "susto" (a type of soul loss with diverse symptoms) that afflicts indigenous peoples in Central America, so the ethnobotanist, often in working with a physician, must be adept at mapping signs and symptoms of indigenous disease states onto concepts of illness understood by Western peoples. Those plants identified by the indigenous peoples as containing healing properties are collected and identified, with samples prepared for bioassay-guided fractionation. In addition, careful notes about possible adverse reactions, dosages, preparation, and application techniques are carefully prepared to assist other members of the drug discovery team. Although the ethnobotanical approach seems to work well for diseases (such as skin fungus or acute viral syndrome) that are easily recognizable by indigenous peoples, other diseases, such as brain tumors or lymphoma, which require advanced techniques for diagnosis, show less hope of being successively treated by drugs discovered during ethnobotanical research.

There are different approaches to ethnobotanical screens. In the consensus approach, developed by Brent Berlin at the University of Georgia, numerous villagers are interviewed with regard to their knowledge of healing plants. Those medicinal plants that are repeatedly mentioned in interviews are prioritized for testing due to their high saliency in the culture. A variant of this approach is to prioritize for study those plants used in common by different villages or even cultures; an ethnobotanical screen based on the latter approach was successfully used by Napo Pharmaceuticals in the discovery of Crofelemer, an antidiarrheal drug derived from *Croton lechleri* (Euphorbiaceae), which successfully completed double-blinded phase III clinical trials.

A different approach to consensus techniques, developed by Michael Balick of the New York Botanical Gardens and Paul Cox of the Institute for Ethnomedicine in Jackson Hole, relies on specialist knowledge known only to healers rather than on knowledge held in common by villagers. In this approach, the healers who are most highly regarded by their societies, who have the greatest knowledge of diseases, and who use the largest repertoire of plant species in their therapeutic practices are asked to rank the efficacy of their healing plants. In a careful trial in Belize conducted in conjunction with the NCI, Balick found that such "powerful plants" identified by healers had a far greater likelihood of generating hits in bioassays.

Nature of Biodiversity-Derived Pharmaceuticals

Microbial Products

In 1929, Alexander Fleming discovered that a petri dish of *Staphylococcus* had become contaminated with a *Penicillium* fungus: Around the fungus in the culture medium was a zone resistant to *Staphylococcus* growth. At Oxford University, a policeman suffering sepsis from a scratch with a rose thorn was successfully treated with a purified extract of *Penicillium*. During World War II, the antibiotic penicillin was isolated. This led to dramatic treatment of infections from wounds and other trauma. Since that time, more than 6000 different antibiotics have been isolated, with more than 1000 having been commercially produced (Samuelsson, 1992). Only a single "natural" penicillin has ever been prescribed as a drug, but more than 100 semisynthetic penicillins have been produced by adding other carboxylic acids to the basic penicillin structure (Sameulsson, 1992). The structure of penicillin, a peptide with a thiazolidine ring, is similar to the structure of the cephalosporins, in which the thiazolidine ring is substituted by a dihydrothiazine ring. *Bacillus brevis* and *Bacillus licheniformis* have been used to produce gramicidin and bacitracin, respectively.

Many new antibiotics and other pharmaceutical products have been obtained from soil samples that are carefully cultivated in sterile petri dishes and fermentation vats. One of the more successful products to be produced from a soil culture is cyclosporin, a cyclic peptide produced from the fungus *Cylindrocarpum lucidum*, originally derived from a Norwegian soil sample. Cyclosporin, a powerful immunosuppressant, was initially seen to have little therapeutic value and remained archived as a refrigerated fungal culture at

Sandoz Pharmaceuticals (now Novartis) in Basel, Switzerland, until mycologist Michael Dreyfuss convinced the management that the product had utility. Today, nearly every heart or kidney transplant patient in the world takes a daily dose of cyclosporin or a similar compound to prevent rejection of the transplanted organ.

Soil samples continue to yield new and interesting bacteria and fungi, whereas exploration of extreme habitats promises to yield important new useful compounds, including those produced by Archea, the recently discovered third domain of life, which produced the enzyme Pfu DNA polymerase. Using recombinant DNA technology, microorganisms can be employed to produce pharmaceutical compounds that they do not ordinarily produce in nature.

Yet the need for new antibiotics looms as a major human health crisis. The routine feeding of antibiotics to livestock to increase their weight, and indiscriminate the use of antibiotics by people around the world, have led to the evolution of antibiotic resistance among many species of bacteria. Most serious is community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA), which is approaching epidemic levels in US hospitals, prisons, athletic teams, and newborn nurseries. CA-MRSA causes rapidly progressive pneumonia and tissue necrosis. Entirely new classes of antibiotics are required to treat CA-MRSA infections that can be quickly fatal. Cyanobacteria, which produce a range of toxic compounds, such as BMAA – which has been linked to motor neuron disease (Cox *et al.*, 2005) – may be one possible source for new antibiotic and antiviral compounds. Recent studies by William Gerwick and his colleagues at the Scripps Institute of Oceanography have yielded a number of anticancer drug candidates from cyanobacteria (Simmons *et al.*, 2005).

Marine Organisms

Marine organisms, particularly invertebrates, are known to produce extraordinarily toxic compounds. Currently, three compounds isolated from marine resources are in preclinical development as possible anticancer agents by the NCI. The marine algal species *Portiera hornemannii* from the Philippines has yielded a drug called halomon, a species of the sponge genus *Lissodendoryx* from New Zealand has produced halichondrin B, and a Caribbean tunicate *Ecteinascidia turbinata* has yielded Trabectedin (ecteinascidin 743), which has been approved in Europe, where it is sold by Zeltia and Johnson & Johnson under the brand name Yondelis for the treatment of soft tissue sarcoma. It is currently being evaluated for treatment of breast, prostate, and pediatric cancers. Another promising marine pharmaceutical is bryostatin from the Californian bryozoan *Bugula neritina*. Bryostatin inhibits melanoma, reticulum cell sarcoma, and lung carcinoma. The discovery of bryostatin will likely lead to new therapeutic concepts in chemotherapy. As previously mentioned (*see* Ecological Screens), Prialt, a neuropeptide derived from cone snail venom, is used to treat intractable pain. Originally marketed by Elan Pharmaceuticals, Prialt was recently acquired by Azur Pharma. It currently is the only nonopioid intrathecal therapy approved for severe chronic pain. Currently, 6000 marine samples are

archived at the NCI for testing, and there is continuing industrial interest in natural products derived from marine organisms (Molinski *et al.*, 2009).

Terrestrial Animals

Terrestrial animals have historically played an important role in the production of certain therapeutic hormones and steroids. Progesterone was first isolated from pig ovaries in 1934. Animals were eclipsed by plants, however, as a source of steroidal precursors when in 1940 Russell Marker discovered that Mexican yams of the genus *Dioscorea* could be utilized to produce diosgenin. There has also been a long-term research interest in venoms produced by snakes as sources of pharmaceuticals. Ancrod, a drug used to treat circulatory diseases, is isolated from the venom of the Malayan pit viper *Agkistrodon rhodostoma*. Recent research, such as that conducted by Matt Ritter and Francis Markland at the University of Southern California, indicates that proteins such as conotoxins found in certain snake venoms can treat cancer tumors (Ritter *et al.*, 2000). And as previously mentioned (*see* Ecological Screens), Byetta, a synthetic form of the peptide exenatide derived from Gila monster saliva, is transforming the treatment of type 2 diabetes. The poisonous secretions of some toads and frogs contain bufotenin. Ethnozoologist Wade Davis has found that secretions of species of *Bufo* were used as psychotropic substances by indigenous peoples in Central America. Epibatidine, from the poison dart frog, is being developed as a possible analgesic. It is likely that other venoms and stings will produce new pharmacological insights.

Terrestrial Plants

Plant-derived drugs are used for a broad spectrum of diseases and include quinine (for malarial suppression), digitalis (for treatment of rapid atrial fibrillation), vincristine (for treatment of pediatric leukemia), tubocurarine (a muscle relaxant used in anesthesia), pilocarpine (for the treatment of glaucoma), and γ -strophanthin (for congestive heart failure) (Table 1). However, in the latter quarter of the twentieth century, very few plant-derived drugs were released to market, even though there was an increase in consumer interest in North America, Europe, and Japan in “natural” plant medicines. Given that less than 1% of the world’s plants have ever been carefully studied for pharmacological activity, it is puzzling that pharmaceutical firms are not rigorously investigating plants as the sources of new pharmaceuticals.

Flowering plants and ferns have traditionally provided the bulk of biodiversity-derived pharmaceuticals, but recent advances in molecular biology and combinatorial chemistry have reduced the pharmaceutical industry’s ardor in studying plants. The popular mythology of industry-supported botanists combing the rainforests for new plant-based leads is simply not true. Currently, there is not a single major pharmaceutical firm that lists among its employees a Ph.D. botanist or an ethnobotanist who works in a drug-discovery program based on plants. Despite the lack of interest by the pharmaceutical industry, both the promise and the impact of plant-derived pharmaceuticals are profound. The World

Table 1 Fifty drugs discovered from ethnobotanical leads

<i>Drug</i>	<i>Medical use</i>	<i>Plant source</i>
Ajmaline	Heart arrhythmia	<i>Rauvolfia</i> spp.
Aspirin	Analgesic, inflammation	<i>Filipendula ulmaria</i>
Atropine	Ophthalmology	<i>Atropa belladonna</i>
Benzoin	Oral disinfectant	<i>Styrax tonkinensis</i>
Caffeine	Stimulant	<i>Camellia sinensis</i>
Camphor	Rheumatic pain	<i>Cinnamomum camphora</i>
Cascara	Purgative	<i>Rhamnus purshiana</i>
Cocaine	Ophthalmic anesthetic	<i>Erythroxylum coca</i>
Codeine	Analgesic, antitussive	<i>Papaver somniferum</i>
Colchicine	Gout	<i>Colchicum autumnale</i>
Demecolcine	Leukemia, lymphomata	<i>Colchicum autumnale</i>
Deserpidine	Hypertension	<i>Rauvolfia canescens</i>
Dicoumarol	Thrombosis	<i>Mellilotus officinalis</i>
Digoxin	Atrial fibrillation	<i>Digitalis purpurea</i>
Digitoxin	Atrial fibrillation	<i>Digitalis purpurea</i>
Emetine	Amebic dysentery	<i>Cephaelis ipecacuanha</i>
Ephedrine	Bronchodilator	<i>Ephedra sinica</i>
Eugenol	Toothache	<i>Syzygium aromaticum</i>
Gallotannins	Hemorrhoid suppository	<i>Hamamelis virginiana</i>
Hyoscyamine	Anticholinergic	<i>Hyoscyamus niger</i>
Ipecac	Emetic	<i>Cephaelis ipecacuanha</i>
Ipratropium	Bronchodilator	<i>Hyoscyamus niger</i>
Morphine	Analgesic	<i>Papaver somniferum</i>
Noscapine	Antitussive	<i>Papaver somniferum</i>
Papain	Attenuate mucous	<i>Carica papaya</i>
Papaverine	Antispasmodic	<i>Papaver somniferum</i>
Physostigmine	Glaucoma	<i>Physostigma venenosum</i>
Picrotoxin	Barbiturate antidote	<i>Anamirta cocculus</i>
Pilocarpine	Glaucoma	<i>Pilocarpus jaborandi</i>
Podophyllotoxin	Condylomata acuminata	<i>Podophyllum peltatum</i>
Proscillaridin	Cardiac malfunction	<i>Drimys maritima</i>
Protoveratrine	Hypertension	<i>Veratrum album</i>
Pseudoephedrine	Rhinitis	<i>Ephedra sinica</i>
Psoralen	Vitiligo	<i>Psoralea corylifolia</i>
Quinidine	Cardiac arrhythmia	<i>Cinchona pubescens</i>
Quinine	Malaria prophylaxis	<i>Cinchona pubescens</i>
Rescinamine	Hypertension	<i>Rauvolfia serpentina</i>
Reserpine	Hypertension	<i>Rauvolfia serpentina</i>
Sennoside A, B	Laxative	<i>Cassia angustifolia</i>
Scopolamine	Motion sickness	<i>Datura stramonium</i>
Stigmasterol	Steroidal precursor	<i>Physostigma venenosum</i>
Strophanthin	Congestive heart failure	<i>Strophanthus gratus</i>
Teniposide	Bladder neoplasms	<i>Podophyllum peltatum</i>
THC	Antiemetic	<i>Cannabis sativa</i>
Theophylline	Diuretic, asthma	<i>Camellia sinensis</i>
Toxiferine	Surgery, relaxant	<i>Strychnos guianensis</i>
Tubocurarine	Muscle relaxant	<i>Chondrodendron tomentosum</i>
Vinblastine	Hodgkin's disease	<i>C. roseus</i>
Vincristine	Pediatric leukemia	<i>C. roseus</i>
Xanthotoxin	Vitiligo	<i>Ammi majus</i>

Health Organization estimates that 85% of the world's population depends directly on plants for medicine, and more than 25% of current prescription drugs have at least one active component derived from a flowering plant. The former statistic, derived principally from developing countries, has provided significant opportunities to contribute to world health by assisting different nations to evaluate the safety and

efficacy of their own pharmacopoeias. Currently, China, Mexico, Thailand, and Nigeria have incorporated traditional plant-based medicines directly into primary health care. An example of the possibilities inherent in this approach has been demonstrated in Thailand, where a potent antiinflammatory compound from the beach plant *Ipomoea pes-caprae* (Convolvulaceae) long used by fishermen to treat stings from

the Portuguese man-of-war was isolated and purified using bioassay-guided fractionation with its structure being determined using NMR spectroscopy. However, rather than testing a pure compound, the Thai researchers conducted a careful, double-blind controlled study of a crude tincture of the plant. It was found to be both safe and efficacious. The resultant tincture can now be bought in any Thai drugstore for a price far less than that of a synthetic drug. The widespread European acceptance of the German Commission E herbal medicines in primary health care is a likely portent of broader acceptability of phytopharmaceuticals in the industrialized world (Blumenthal, 1998).

However, several plant-based pharmaceuticals have been recently released or are under current preclinical or clinical evaluation. Taxol, discovered during the NCI random screen, has received FDA approval for treatment of breast and ovarian cancers. For AIDS, currently five plant-derived compounds are in preclinical development. Derived from the resin of *Calophyllum lanigerum* (Guttiferae) in Malaysia, calanolide A has shown intense activity against HIV-1, as has costatolide derived from a related tree *Calophyllum teysmannii* from the same region. Michellamine B from the leaves of the Cameroon vine *Ancistrocladus korupensis* (Ancistrocladaceae) has also shown antiHIV activity, as has conocurvone derived from *Conospermum* (Proteaceae) shrubs found in Western Australia. Because of its use in indigenous medicine, the fifth member of this anti-AIDS quintet, prostratin, perhaps deserves in-depth discussion as a case study of recent developments in this field.

For many years, Samoan healers have used the stem wood of a small understory rainforest tree, *Homalanthus nutans* (Euphorbiaceae), to treat a disease known as "fiva samasama," characterized by yellowing of the eyes, dark urine, jaundice, and fevers; this disease was subsequently determined to be hepatitis. To prepare the remedy, the wood of *Homalanthus* is macerated into a clean cloth, which, like a tea bag, is immersed into boiling water. After steeping, the contents of the tea bag are discarded, and the resultant tea is drunk by the patient. Samples of the healer preparations and the plants were tested against an *in vitro* HIV-1 bioassay in a collaboration between Paul Cox and NCI researchers Kirk Gustafson, John Cardellina, II, John Beutler, Peter Blumberg, Gordon Cragg, Michael Boyd, and others at the Natural Products Branch of the NCI (Gustafson *et al.*, 1992). The healer mixture and the crude plant extracts were found to protect cells from death by HIV-1, even though there was no evidence of reverse transcriptase inhibition or other marked inhibition of the mixtures to the virus. Bioassay-guided fractionation yielded a pure compound, prostratin (12-deoxyphorbol-13-acetate). Although phorbols, similar in structure to prostratin, are potent tumor promoters, *in vivo* studies by Peter Blumberg at the National Institutes of Health showed prostratin to be an antipromoter, even though it activates protein kinase C. The NCI advertised prostratin as a potential new component of a combination therapy for AIDS. The NCI required any pharmaceutical developer of prostratin to negotiate directly with the Samoan government for a fair and equitable return of a portion of any royalties. Such negotiations between the Samoan government and the AIDS Research Alliance (ARA) led to an agreement to return 20% of ARA's profits from

prostratin to Samoa to be divided between the government, the village, and the healers. Similar negotiations led the University of California, Berkeley, to sign an agreement with the Samoan government to return 50% of the commercial proceeds of the prostratin genes to Samoa (Cox, 2001). In addition, preroyalty benefits provided to the village through the conservation organization Seacology have now exceeded \$500,000. Although prostratin is currently being developed as an antiHIV drug, its utility in the treatment of hepatitis has yet to be determined.

Biodiversity and Ethics

The Convention on Biodiversity

The Convention on Biological Diversity (CBD), often referred to as the Rio Treaty, provided a broad basis in international law for the discovery and development of pharmaceutical compounds from biodiversity. To promote the conservation and study of biodiversity, the parties to the CBD agreed that each nation has sovereignty over its own biological resources. Collection and development of these resources can thus proceed only with express permission of the national government. What initially was seen as a mechanism to accelerate investigation and conservation of biological resources by facilitating international cooperation has been criticized by some as an impediment to research. Many countries, fearing uncompensated exploitation of their national biological resources, have either closed their doors to international scientific exploration or caused the process of obtaining research permits to be extraordinarily slow and difficult. Given the history of colonial exploitation of biological resources, with little thought given to equitable sharing of benefits of discoveries based on biodiversity, such reaction by developing countries is understandable. If the processes of biodiversity were static and extinction quiescent, closing national boundaries to scientific investigation would have little long-term consequence; however, given the rapid rate of extinction (the IUCN estimates that one-eighth of the world's plants are threatened or endangered), nations that close their doors to scientists may unwittingly ensure that their biodiversity will vanish without any significant appraisal of its economic value. An interesting exercise would be to compare the relative difficulties of obtaining permits to collect and pharmacologically analyze 50 mg plant samples from various countries versus the difficulties in obtaining permits to clear cut and export entire rainforests: Too often, those who destroy biodiversity are facilitated while those who seek to study it are hindered.

Given the relative lack of interest of the pharmaceutical industry in investigating biodiversity as a source of new pharmaceuticals, and the occasionally unreasonable expectations placed on pharmaceutical firms for large initial payments and high percentages of royalties, many pharmaceutical firms that once had nascent interest in natural product chemistry have retreated to computer modeling and combinatorial chemistry as the sole engines of pharmaceutical discovery. Although this situation may change if new, important drugs are discovered from biodiversity, it is crucial that

investigators adhere to high ethical standards. Training local scientists, obtaining informed consent from village chiefs or elders before initiating research, depositing duplicates of all collected specimens with local or regional herbaria, and vigorously protecting indigenous intellectual property all help to promote understanding and collaboration. Investigators who fail to heed such standards or, worse, ignore local laws and international treaties, imperil not only their own research programs but also conservation of the very biodiversity they purport to study.

An interesting, and perhaps unintended, consequence of the CBD has been its impact on the rights of indigenous peoples. By granting sovereignty over all biological resources to national governments, the convention in a sense can disenfranchise indigenous peoples, particularly in countries with a history of mistreating them. Is it reasonable that a plant that has been developed and studied through generations of indigenous healers should be considered the sole property of a distant (and perhaps hostile) national government? However, by stating in article 8(j) that indigenous peoples bear some consideration, the architects of the Convention on Biodiversity provided indigenous peoples with one of the first broadly accepted international treaties that explicitly recognizes their existence and aspirations. Article 8(j) requires signatory nations to (1) respect, preserve, and maintain traditional knowledge; (2) promote wide application of traditional knowledge; and (3) encourage equitable sharing of benefits from traditional knowledge. Many indigenous groups hope that their voices will increasingly be heard and considered at meetings of the parties to the convention.

In October 2010, the COP 10 Biodiversity meetings in Aichi-Nagoya, Japan, resulted in the adoption of the Protocol on Access and Benefit Sharing by the parties to the convention. It is hoped that this international agreement will continue to encourage analysis of biodiversity for new pharmaceuticals and the equitable sharing of benefits with biodiverse-rich countries and indigenous peoples. Benefits in the COP 10 agreement include technology transfer, research results, and royalty sharing from patented products.

Bilateral Agreements on Pharmaceutical Research

There have been attempts to directly negotiate with national governments for rights to perform pharmaceutical research on biodiversity. One of the best known of these arrangements was a remarkable agreement entered into by the government of Costa Rica and Merck Pharmaceuticals. Under the INBio Agreement, Merck received rights to survey the flora and fauna of Costa Rica in return for a share of the proceeds of any new discovery and for a payment of \$1 million used to support the training of local investigators and development of a national inventory of Costa Rican biodiversity. Costa Rica has been very innovative in training local people in biological survey techniques. Termed "parataxonomists," these local people, often with profound folk knowledge of organisms in their environment, are trained in modern techniques of collection and vouchering. By devoting the bulk of the Merck funds to biodiversity research, the government of Costa Rica has

guaranteed that the people of Costa Rica and indeed the world will benefit for many years.

Indigenous Intellectual Property Rights

In ethnobotanical approaches to drug discovery, it is important that the contributions of indigenous people be appropriately recognized and compensated. Often, indigenous values, particularly views of fairness and equability, differ dramatically from those of Western societies. Many Western societies highly value individualism, rationalism, and candor in expression, whereas in many indigenous societies, values such as respect for village elders, proper regard for ancestors and deities, and recognition of the sacred nature of living organisms play a crucial role. Frequently, indigenous peoples also have very distinct views about appropriate behavior and dress within a village.

It is important that Western investigators dealing with indigenous peoples show appropriate respect for indigenous values. Indigenous mores and folkways should not be violated by investigators, and the position of traditional leaders, chiefs, and village councils should be respected rather than eroded. This may mean, for example, that Western scientists do not publish biodiversity information considered secret by indigenous people or do not venture into areas considered to be taboo. Respect can be communicated by completely informing such leaders and village councils about the scope, nature, and possible impact of biodiversity research. Informed consent of traditional leaders is crucial when discussions are held concerning fair and equitable returns for indigenous intellectual property: Traditional leaders cannot make informed decisions concerning biodiversity research unless they possess accurate information concerning the nature and value of the research. Rather than imposing Western values of fairness and equability on indigenous peoples, investigators should regard indigenous peoples as coequals in any negotiations and seek solutions that meet indigenous rather than Western concepts of fairness and equability. Often, traditional leaders are not familiar with Western culture or conversant in Western languages, but the temptation to use Western-educated elites as surrogates for traditional leaders in negotiations should be avoided (Cox, 2000b).

For many indigenous peoples, conservation is a keenly felt need, a means of both perpetuating their culture and demonstrating respect to Earth and to their ancestors. Innovative approaches to assisting indigenous peoples in conservation can be successful if indigenous peoples truly control the conservation initiatives. The Terra Nova biomedical reserve in Belize and the Falealupo Rain Forest Reserve in Samoa are examples of indigenous conservation begun by Western scientists that are now completely controlled by indigenous peoples (Cox, 2001). Culturally appropriate acknowledgment of indigenous collaborators such as including publication of scientific abstracts and reviews in indigenous languages and coauthorship of papers and books with indigenous collaborators are examples of the best practices currently employed by ethnobotanists. Protection of indigenous financial interests often requires vigorous efforts on the part of Western scientists, who need to assist indigenous leaders in dealing with

lawyers, commercial firms, or governments that may not completely appreciate indigenous property rights. Entering into any collaborative project, including ethnobotanical research, with indigenous peoples imposes a responsibility on the part of scientists to protect indigenous rights. It should not be surprising, then, that some of the most persuasive Western advocates of indigenous rights have been scientists who have lived and worked closely with indigenous peoples.

Rights of the Sick and Afflicted

In an era in which life itself increasingly appears to be a commercial commodity, it might appear quaint to raise the possibility that stakeholders in biodiversity research include others than sovereign nations, pharmaceutical firms, and indigenous peoples. However, moral rights are not always harmonious with property rights: Most societies, for example, believe that small children have an inalienable claim on their parents for support, even though children do not possess legal title to any of their parents' possessions. Similarly, the constitutions of many nations now recognize rights of mothers, children, and other citizens to adequate nutrition and minimal health care. In former eras, the sick and afflicted were believed to have certain claims on healing plants and substances. Although it is unlikely in the modern market economy that the sick and afflicted will ever be granted a significant voice in biodiversity research, ill people remain often unseen but tangible stockholders in biodiversity-based pharmaceutical research. The sick and afflicted, and their families and societies that support them, stand to lose if the world's biodiversity is thoughtlessly destroyed before it can be evaluated for pharmaceutical potential.

Glossary

Artificial ecosystems Ecosystems dominated by human artifacts and human induced material and energy flows.

Biosphere people People enjoying access to resources garnered from the entire biosphere and made available through markets.

Biosphere reserve An international conservation program aiming to protect representative ecosystems throughout the world in ways compatible with development efforts.

Ecological footprints Spatial coverage of ecological impacts consequent on the activities of a given group of people.

Ecological refugees People that have lost access to their traditional base of natural resources yet have very limited access to resources through markets.

Ecosystem people People meeting the bulk of their resource requirements from a limited area near their habitation through gathering or low input agriculture and animal husbandry.

Resource catchment Locality from which the resources consumed by a group of people are derived.

Wealth and its obverse, poverty, is today reckoned in terms of the capacity of a person or groups of persons to obtain goods and services through exchanges in the marketplace. The bulk of such goods and services are partly or wholly products of intensively managed or artificial ecosystems; crop fields, plantations, shrimp ponds, mechanical fishing fleets, factories, towns, and cities. Most of these intensively managed or artificial ecosystems tend to harbor low levels of biodiversity. Rich people are then those with extensive access to produce of managed or artificial ecosystems supporting low levels of biodiversity; poor people have very limited access to such produce. Ecosystems harboring high levels of biodiversity are, on the other hand, natural or semi-natural ecosystems with low levels of human demands for their produce. Rich people rarely live in close vicinity of such ecosystems, though they may visit them for recreational purposes. Groups of poor people may, on the other hand, permanently live in their vicinity. In some cases, the poor control and serve as the stewards of such biodiversity rich ecosystems. More often though many such biodiversity rich ecosystems are subjected to overexploitation, primarily to meet the large resource demands of the rich, often living far away, with the local poor serving as agents of the resultant destruction of biodiversity. Large numbers of poor also live permanently in the vicinity of biodiversity poor, intensively managed, or artificial ecosystems. There is then no simple relationship between poverty and biodiversity; the equations vary greatly from context to context.

Of Ecosystems and People

To appreciate these complexities, one must tease out the many contexts. These may be viewed along two axes; one of the extent to which ecosystems have been transformed through human interventions, and the second of the manner in which

people relate to the world of nature, to the world of manufactured artifacts, and to each other. The terrestrial and aquatic ecosystems may be classified into four major categories: (a) natural ecosystems, which are subject to very low levels of human demands because of their inaccessibility; (b) natural and semi-natural ecosystems, including low-input agricultural systems subject to higher levels of human demands; (c) ecosystems managed intensively for biological production; and (d) largely artificial ecosystems dedicated to industrial production and organized services. Building on [Dasmann's \(1988\)](#) pioneering work, we may, for our purpose, classify people into four major, largely inclusive categories; (a) autonomous ecosystem people, (b) subjugated ecosystem people, (c) biosphere people, and (d) ecological refugees. Ecosystem people have limited access to sources of energy other than human and livestock muscle power and to the more sophisticated artifacts. They gather or produce most of the resources they consume from their immediate surroundings, from the forest, scrub, rivers, or seas and from low-input cultivation. In some of the more inaccessible corners of the world, the ecosystem people are still autonomous. However, over most of the earth they have been subjugated by the biosphere people and have very limited control over their own resource base of natural and semi-natural ecosystems. They gather and produce little that can fetch value in markets and therefore have very limited access to produce of intensively managed and artificial ecosystems. The biosphere people owe their dominant position to their extensive control over artifacts and additional sources of energy. They engage in energy-intensive agriculture, animal husbandry, aquaculture, or in organized services or industrial production and generate much of value in the markets. They have large ecological footprints thanks to their substantial purchasing power; their resource catchments are vast encompassing all of the biosphere, bringing to them goods and services from all over the earth. This confers on them the ability to take over

resources in demand by the ecosystem people, catalyzing transformation of natural and semi-natural ecosystems into those managed intensively to meet their own demands or, in some special cases, conserved as natural or semi-natural ecosystems for recreational purposes. In the process, they often deprive ecosystem people of access to their traditional resources; this may convert them into ecological refugees. Ecological refugees are then people with attenuated access to resources of natural and semi-natural ecosystems, with little purchasing power to access products of intensively managed and artificial ecosystems. They often end up constituting the unorganized labor force in tracts of intensive agriculture and urban settlements (Gadgil, 1995; Gadgil and Guha, 1995).

Autonomous People

I propose to explore the relation between poverty—or wealth—and biodiversity in this framework of different categories of ecosystems and of people. **Table 1** summarizes the relationship and notes the examples that are discussed later at some length. All of these derive from my own fieldwork in India; I use them purely because I know them well. However, they do represent broader patterns encountered in other parts of the world. Not all 16 cells of the matrix are occupied; moreover our focus is on poverty, and we shall therefore not elaborate on the relationship of the biosphere people with biodiversity, except as they impact on the ecosystem people or

ecological refugees. There are relatively few examples of truly autonomous ecosystem people, people fully in control of largely natural ecosystems with very light human demands, and in consequence with high levels of biodiversity. Inhabitants of Sentinelese island (11°30' N lat. 92°15' E long.) in the Andaman-Nicobar chain in the Bay of Bengal provide one such example. These relatively inaccessible islands harbor tropical rain forest biota with high levels of endemism (i.e., of species restricted to this chain of islands). They were inhabited by a number of hunter-gatherer tribal groups, without knowledge of metal tools, with the exception of the Shompens of Nicobars who had a more advanced fishing economy. The British colonized the islands in the mid-nineteenth century, an attempt that was strongly resisted by the indigenous people. By the 1870s the resistance was overcome and as a consequence many of the tribal populations either drastically declined or were exterminated. During British times the islands primarily served as a convict colony, with many of the released convicts settling down to agriculture (Superintendent of Government Printing, 1909). After independence in 1947 the islands were used to create agriculture based settlements of many people displaced from then East Pakistan (now Bangladesh), as well as to supply forest resources for rapidly growing forest based industries, especially plywood (Saldanha, 1989). As these were progressively overused and exhausted leading to substantial erosion of biodiversity, pressure has built up to overcome the resistance of the tribal groups still holding out to open up their territories to commercial forest exploitation. Two of the tribal groups, however, do continue to retain hold over their territories; these are Jarwas and Sentinelese. Jarwas live on the larger South

Table 1 Variety of people-ecosystem contexts, with specific examples

<i>Ecosystems</i>	<i>People</i>			
	<i>Autonomous ecosystem people</i>	<i>Subjugated ecosystem people</i>	<i>Biosphere people</i>	<i>Ecological refugees</i>
Inaccessible natural/ seminatural ecosystems	Poor in modern economic sense, with access to high levels of biodiversity, e.g., Sentinelese islanders	—	—	—
Accessible natural/ seminatural ecosystems	—	Poor in modern economic sense, serve as agents for destruction of biodiversity, e.g., Gangtes of Manipur, sometimes as stewards, e.g., Village Forest Committees, protectors of Saranas	Visitors for recreational/ commercial use	Poor in modern economic sense, serve as agents of destruction of biodiversity, e.g., Panshet peasants, Maldharis of Gir
Ecosystems managed intensively for biological production	—	—	Well off in modern economic sense, promote low biodiversity production systems	Poor in modern economic sense, alienated from biodiversity, e.g., Jharkhand tribals
Artificial ecosystems dedicated to industrial production/ organized services	—	—	Well off in modern economic sense, promote high biodiversity systems for recreational purposes	Poor in modern economic sense, alienated from biodiversity, e.g., Jharkhand tribals

Andaman and Baratung islands (12°0' N–12°20' N lat. 92°45' E–92°55' E long), about two-thirds of which has been colonized by immigrants and subjected to forest exploitation. Their territory is therefore easily accessible; it is, however, stoutly defended by Jarwas with their bows and arrows. There are ongoing attempts to overcome this with the aid of a major road passing through their territory. This Jarwa territory remains much richer in biodiversity than the rest of the islands; Jarwas are, however, poorer in a modern economic sense with access to very few and simple artifacts. The Sentinelese live on a smaller island, which remains entirely under their control. This island too is very rich in biodiversity; the Sentinelese are also very poor in a modern economic sense. Presumably Jarwas and Sentinelese do not themselves have concepts of wealth and poverty or biodiversity (Bhattacharyya, 1993; Gadgil, 1998). They apparently do have concepts of members of their own groups as opposed to aliens and desirability of excluding aliens from their territory. They remain poor in the modern sense because they have successfully maintained themselves in isolation; for the same reason their territory retains high levels of biodiversity.

Subjugation: Political and Economic

The vast majority of the ecosystem people of the world are, however, no longer isolated in this fashion. In no case do they seem to have voluntarily sought to integrate with the larger society dominated by the biosphere people. Rather the biosphere people have sought to integrate them in order to access resources of their territories, as well as to utilize their labor. The process of such integration tends to proceed through several stages involving political subjugation, followed by economic subjugation. Such subjugation is accompanied by a reduction in levels of access of the people to the biodiversity resources of their own localities; though simultaneously they may have enhanced access to other resources through market channels, thereby implying a reduction in the levels of their poverty in modern economic terms. The process is also generally accompanied by an erosion of biodiversity driven by overexploitation of natural resources to meet outside demands with the subjugated ecosystem people often serving as agents of such erosion.

These processes are the dominant form of interplay of poverty and biodiversity in the world today, and we propose to illustrate them through a series of case studies. The most detailed case to be presented would involve Gangtes, one of the Kuki tribes of Churhandpur district (23°4'–25°50' N lat. and 93°–94°47' E long.) of the northeastern state of Manipur on the India-Myanmar-China border, since this illustrates the complete sequence from autonomy through political and then economic subjugation (Gadgil, Hemam, and Reddy, 1997; Hemam, 1997). Like many other Kuki and Naga groups, Gangtes continued head hunting well into the nineteenth century. At that time, there were no roads so that people had to walk for several days to reach markets where they could exchange hand-woven cloth or honey for iron tools or rice. These journeys were hazardous as they could involve passage through territories of alien tribes. Each settlement was in consequence a largely self-sufficient and self-governing entity. Their base of subsistence was shifting cultivation with long

fallows of about 15 years. There were no fixed village boundaries and individual social groups presumably shifted around from time to time. The settlements were located on hill-tops; the valleys were considered unsafe and more vulnerable to raids from alien groups. Among Gangtes, hereditary village chiefs determined through primogeniture made all group-level decisions in consultations with a council of elders. They assigned lands for cultivation and annually received about 16 kg of grain from each family in the group as a tribute for use in entertaining any visitors. In the course of cultivation the densest, tallest forest tracts were left alone as requiring too much labor for conversion to fields; the more recent fallows were also avoided. The people worshipped many natural elements including mountain peaks, streams, plants, and animals. They strictly protected patches of sacred groves called gamkhal as also other spirit possessed lands called nungens. Also protected were bamboo groves called mavuhak from which bamboo may be extracted only for house construction, but the shoots, much relished as food, were left alone. This preserved a luxuriant vegetation, which led Captain Pemberton to remark in 1835: "I know no spot in India, in which the products of the Forests are more varied and magnificent but their utility is entirely local" (Pemberton, 1835).

The process of political subjugation of Gangtes began in the late nineteenth and early twentieth centuries with the development of incipient links with mainstream India, then ruled by the British. Initially, the British did not so much want access to resources of Churhandpur as of the much richer Myanmar. Hence they wanted to ensure safe movements of British troops in the hill tracts of Manipur bordering Myanmar. A people without fixed, well-defined villages and with traditions of killing aliens coming into their territories were an obvious threat. The British therefore concentrated on fixing village boundaries and assigning land ownership. Given the Gangte system of hereditary village chiefs having a major role in all decisions including assigning land for shifting fields, they decided to confer on the chiefs all ownership over land, converting others into tenant farmers from a legal perspective. This move then formally introduced wealth and poverty to the Gangte society. However, during the British reign this made little operational difference in most areas, with no acceptance of private property in land by Gangtes, except in the Churhandpur town area beginning in the 1930s. Elsewhere Gangte community members continued to pay the village chief a tribute of 16 kg of grain as before. The late nineteenth and early twentieth centuries also witnessed the gradual spread of Christianity. Christianity rejects the attribution of sacred qualities to elements of nature and, consequently, taboos against killing of certain animals or felling of certain patches of forests like gamkhal. Conversion to Christianity therefore began to slowly erode the traditional belief system underlying these conservation practices.

In this phase of political subjugation there was little change in the economy. The road network remained extremely limited and the Gangte communities remained almost totally self-sufficient in terms of resource use. The fallow cycles for shifting cultivation were still long, and substantial areas of forest retained protection in forms of sacred groves. However, by introducing the legal concept of private ownership and a religion that questioned attribution of sacred qualities to

nature, this phase did set the stage for the radical changes that followed independence; but unlike on the mainland, this political subjugation had limited impact in the absence of an access to markets and therefore of any attempt at economic subjugation.

Market Forces

The British were prompted by the march of the 'Free India Army' fighting in collaboration with the Japanese into Manipur through Myanmar to strengthen the road network of Manipur on a war footing, laying the foundation for the rapid development of transport, communication, and commodification that began on independence in the 1950s. This was consistent with the policies of economic development and national integration adopted at the time of independence. These development policies also encouraged forest based industries by offering them many resources, including wood, at highly subsidized rates (Gadgil and Guha, 1992, 1995). As the production of these industries grew at a rapid pace, the demands outstripped supplies leading to severe overexploitation. Such overexploitation was facilitated by the fact that there was no social group sufficiently motivated to ensure a more sustainable pattern of resource use with a secure enough control over the resource stocks. Access to markets meant that a community no longer suffered an inevitable shortage of resources if those from their own vicinity were overused and exhausted. Neither would such a difficulty be experienced by an industry drawing resources from a larger spatial scale. Market access therefore reduced the motivation of the various parties concerned, local communities, such as those of Gangtes, as well as other consumers such as the plywood industry for restraints on levels of harvests. At the same time conversion to Christianity eroded the conservation ethos of local communities grounded in attribution of sacred qualities to various natural elements. Linkages to the larger national society also diluted the control of any one agency over any given resource base by bringing a variety of actors into play. Thus in the autonomous phase where a person might even be killed while passing through alien territory, there was a clear-cut control by a local community. In the phase of political subjugation this was legally recognized as the control in terms of ownership by the local chieftains. But in the post-independence phase of economic subjugation the state Forest Department has stepped in to claim control over forest lands and forest resources. How this claim is to be reconciled with the claim over land ownership by the Gangte chiefs has not been clarified. This uncertainty has affected the security of resource control by both parties. At the same time, the traditional authority structure of a Gangte village community headed by a hereditary chief with a council of elders has also been affected by the institution of a democratically elected village council. There are continuing contradictions in this system as well since the hereditary chief remains at the head of the elected village council. Under these circumstances, forest resources of Gangte villages have been affected by demands greatly exceeding sustainable yield levels. These demands are no longer local, but reflect the markets not only of remaining parts of the state of Manipur, but the rest of

the country as well. Indeed market pulls come from even beyond national borders as Indian plywood was over some periods exported in substantial quantities to the mid-east.

The traditional Gangte society is largely egalitarian. This situation has radically changed with the linkages to the market economy as the chiefs are now motivated to take advantage of the individual ownership of vast tracts of lands assigned to them. Their assertion of such ownership rights over the land or the tree resources standing on the land is against customary norms. The chiefs therefore press home such assertions to a variable degree, depending on the level of the expected monetary gain. The higher the level of expected gain, the more firmly is ownership asserted by the chiefs. In general, such gains are highest close to the market town of Churchandpur, they decline with distance from the town and from the roadhead. As Table 2 shows, this is reflected in the chiefs forcing all cultivators to buy plots of land close to the town, while in remote areas all that the cultivators pay is the traditional annual tribute of 16 kg of grain. Similarly close to the town community members pay a royalty to the chief even for collection of fuelwood, while further afield they have free access to even more valuable timber.

Land Use Changes

This process of over-exploitation of forest resources has also shaped patterns of use of land. Since the forest resources bring in the highest levels of net profits closest to the market town of Churchandpur, all tree stocks have been exhausted in this area. In response, settled cultivation on terraced fields with very low levels of crop diversity such as monocultures of pineapple has replaced the much more biologically diverse shifting cultivation. In more remote areas too, commercial monoculture plantations have been taken up of species like Agor (*Aquilaria aquatocha*), the highly valuable wood that was the first to be exhausted even from areas far from market.

The traditional land-use pattern of Gangtes included leaving aside substantial areas as gamkhals, or so-called village forest reserves (VFR), as well as bamboo reserves and other spirit lands. These practices have been completely abolished in villages close to market towns where land and its produce have acquired high commercial value. In some of the more remote villages the practice of protection of a VFR encircling the settlement has been revived following recognition of its value as a firebreak preventing the spread of fire to the settlement during the slash and burn operations (Gadgil, Hemam, and Reddy, 1997). The traditions of protection of such forest patches still continue in other more remote areas.

Links to markets has meant access to many new goods such as soaps and transistor radios for the Gangtes; goods that need cash for purchase. Sale of timber, fuelwood, and other forest produce such as cane is their only source of cash. But generation of this cash has led to a reduction in the return of nutrients to the fields in slash and burn cycles with a depletion of the standing tree stocks. This has reduced the levels of productivity of shifting cultivation (Ramakrishnan, 1992). The spurt in population growth, favored by introduction of modern health care systems, especially control of malaria, with a rate as high as 4% in some of the north eastern hill

Table 2 Resource ownership, sharing, and utilization patterns among different sections of Gangte tribe at different levels of accessibility and modernization

	<i>Shifting cultivation area</i>		<i>Settled agriculture area</i>	<i>Town area</i>
	<i>Less accessible</i>	<i>Easily accessible</i>		
1. Ownership	Village chief	Village chief	Private	Private
2. Commercialization of forest and current forest condition	Little commercial exploitation and less degradation	Under heavy commercial exploitation and degraded condition	No forest	No forest
3. Onset of commercial forest exploitation	Still untouched, except for domestic use	Early 1970s	Early 1950s	Early 1930s
4. Current status of exploitation	Little exploited, good forest cover	Heavily exploited, degraded forest	Completely exhausted	Completely exhausted
5. Collection of timber	Free access	Pay royalty to the chief	No collection	No collection
6. Collection of fuelwood	Free access	Free access for domestic use	Pay royalty to the chief	Pay royalty to the chief
7. Maintenance of VFR ^a and Bamboo reserve	Still intact	No more	No more	No more
8. Traditional rights of resource sharing and use	Still followed	All have disappeared except for free use of shifting fields and fuelwood collection for domestic use	No more	No more
9. Collection from forest	Fuelwood, wild vegetables, timber and other NTFP ^b	Fuelwood, wild vegetables, timber, and other NTFP	Fuelwood collected from forests of other villages	Occasional collection of fuelwood from nearby forests
10. Land use	Shifting cultivation	Shifting cultivation, terraced cultivation	Wet rice cultivation, pineapple plantation	Habitation
11. Commercial crop plantation	Chili and other vegetables	Banana, chili and vegetables	Pineapple, ginger, and other vegetables	Habitation
12. Energy use	Human muscle power, fuel-wood, and little use of fossil fuel	Human muscle power, fuelwood, and little use of fossil fuel	Human muscle power, animal power, fuel- wood, fossil fuel, and electricity	Fuelwood, electricity, fossil fuel, and less use of human and animal muscle power

^aVillage Forest Reserve (VRF).^bNontimber Forest Produce (NTFP).

areas has also increased the pressure on land and led to a shortening of fallow cycle and a reduction in productivity of shifting cultivation. The net result is that today Gangtes depend on market for about 30% of their food requirements and over 50% of other needs (Hemam, 1997).

Value Appropriation

These cash requirements are met from harvests of forest produce, either through sale or through wages earned as laborers in tree-felling operations taken up by contractors. With the assertion of land ownership and demand for royalty by chiefs, part of the profits go to them. However, the chiefs are unfamiliar with the skills of development of infrastructure such as roads, organizing transport, and marketing of forest produce. As a result outside contractors carry out most of the timber harvesting operations, retaining a bulk of the profits for themselves. Thus in the early 1990s in Nalwan village the contractor paid Rs. 50,000 (US \$ 1600) for rights to harvest timber from an area of over 1000 ha. A conservative estimate of the value of timber thus accessed is Rs. 60 million given a standing stock of 100 tonnes/ha and price of timber at

Rs. 600/tonne. The chief was then paid less than 1.0% of the timber value. Of course, the contractor would have to invest in labor charges, making roads, and transport. Nevertheless, it is clear that bulk of the cash income flows to the contractor, a part to the chief, and a very small fraction to members of Gangte community. The Gangte use this cash to meet their routine requirements. None of it is saved or invested productively in ventures such as developing horticultural plantations to replace shifting cultivation fields. In the long run then the whole process of forest resource use taking place today is leading to exhaustion of these resources with little gains for the Gangte community members.

Today the Gangtes have greater access than they had earlier to goods on the markets and are in that sense richer, though this access is still extremely limited and by all criteria they are quite poor. However, at an earlier time when they were poorer in terms of market access, they had more secure and more equitable rights over land and substantial access to biodiversity and other natural resources; this has drastically reduced. The erosion of biodiversity this transformation has accompanied has in part been driven by the desire of Gangtes to acquire cash; however, the real driving force behind the loss of biodiversity lies in the demand for forest produce by the

biosphere people. Much of the wood of Manipur has been used for manufacture of plywood, and all the value added in this process has been appropriated by those already rather well off, controlling trade and industry of mainland India. The transformation has also witnessed a loss of the traditions of conservation of biodiversity, such as those of protection of sacred groves, by relatively poor people like Gangtes.

Gangtes thus provide an excellent case study of the different stages and processes involved in the transformation of autonomous societies of ecosystem people with access to high levels of biodiversity, but with little access to manufactured artifacts into societies that have lost control over their base of living resources, often turning into instruments of depletion of these resources. Thus subjugated, the ecosystem people may end up with some, though often insignificant, enhancement in their access to artifacts, but with significant losses in their access to biodiversity.

Ecological Refugees

Gangtes have come under the influence of the state and the market economy relatively recently. True, most of them have lost all legal claims over land or forest resources, and the claims of Gangte chiefs over large tracts of land are being contested by the Forest Department; nevertheless, in fact, Gangtes still control extensive tracts of forested land. This level of autonomy is unusual on the Indian subcontinent where state authority has been holding sway for several centuries. One such unusual area is that of Maharashtra Western Ghats, where the local peasants had retained a considerable measure of autonomy by virtue of their active role in the Maratha armies of the seventeenth and eighteenth centuries. The British were reluctant to offend them on the defeat of Marathas in the early nineteenth century. As a consequence they were permitted to continue their shifting cultivation, which was banned over much of the remainder of the subcontinent. Individual peasants, rather than any chiefs were assigned land ownership among the Marathas. So while poor in modern economic terms because their hilly terrain permitted only very restricted access to the markets, these peasants lived in tracts rich in forests and biodiversity with full rights over the resources till the time of independence. The tract was also rich in water resources with annual precipitation in excess of 3000 mm.

On independence the Indian nation state geared itself to tap these rich water resources to promote economic growth with the help of irrigation and hydroelectric projects. One such irrigation project was launched in the Panshet valley to the west of Pune, the old capital of Marathas (18°30' N lat.–73°40' E long.). The Indian state has assumed extensive powers of acquisition of land for public purposes and all the more fertile low lying paddy land of the Panshet valley was taken over at low rates of compensation. The peasants still retained ownership over their hill lands above the submersion level. This had been traditionally under long fallow shifting cultivation during which mango and *Terminalia chebula* trees, both producing fruit of considerable value, were left intact. However, as roads reached Panshet valley to facilitate the dam construction work, these trees caught the attention of charcoal merchants. These merchants worked in collusion with the

government officials in charge of land acquisition to persuade the peasants to sell the trees at exceedingly low prices with the assurance that the peasants would soon be resettled with alternative farmland far from Panshet valley. Most peasants sold the trees, and there was a massive spurt of deforestation in the 1950s during the construction of the dam, the trees being primarily used to produce wood charcoal for consumption in Pune. The peasants, however, were never provided alternative agricultural land elsewhere and have continued staying on hill slopes above the dam for the past 40 years, while some of them have migrated to Pune, primarily to work as unskilled labor. The entire catchment has been devastated by the initial deforestation in the 1950s followed by continual, ever more intensive cultivation of hill slopes by the impoverished peasants. Today the peasants are poor in every sense and live in an environment depleted of biodiversity. They have served as agents of this destruction of biodiversity that has only benefited the charcoal merchants of Pune and provided citizens of Pune with a relatively inexpensive fuel for a period of few years. Thus subjugated, these ecosystem people may be said to have been turned into ecological refugees (Gadgil, 1979).

Our next case study is that of the tribal populations of the so-called Jharkhand tracts of the states of Bihar and West Bengal (22°0'–24°0' N lat. 84°0'–87°40' E long.). This region adjoins the old, thickly settled Gangetic plains that were the nucleus of the 2000 year old Magadha empire extending over much of the Indian subcontinent. Emperor Ashoka of Magadha is famous for his conquest of and subjugation of the tribes in the extensive hilly tracts that border the Gangetic plains (Gadgil and Guha, 1992). This part of the country also fell rather early to British colonialists, who quickly established a hold over the region during the second half of the eighteenth century, far more firm than that over the Maratha Kingdom discussed earlier. The forests of Jharkhand are rich in sal (*Shorea robusta*), an important timber for the production of railway sleepers. This was a resource much valued by the British who therefore acted firmly to ban all shifting cultivation by the tribal people in the early nineteenth century. The forests were also taken over either as a property of the British government or that of private landlords. Where the tribal villages were a part of the government-controlled forest lands, the tribes were totally deprived of any rights to forest resources. Unlike with Gangtes, the landlords too did not come from among the tribes themselves. They came from other castes at a higher level in the hierarchy. These landlords then exploited the lower caste or tribal tenants on their lands quite ruthlessly. The "Jharkhand" tribals were therefore subjected to extreme political as well as economic subjugation as early as the first half of the nineteenth century. Their only earnings came from work as poorly paid tenant farmers or as forest laborers along with sale of some minor forest produce at extremely low rates. They then have a long history as poor people serving as agents of destruction of biodiversity.

These Jharkhand tribals are among the most striking example of ecological refugees of the country. They have served as the most mobile source of very inexpensive, unskilled labor in many contexts. One of the major economic enterprises under the British rule was the development of tea estates replacing the rain forest of Brahmaputra valley in northeastern India. This involved wholesale destruction of biodiversity.

While the plantation owners were British, the laborers responsible for actual destruction of biodiversity were mostly Jharkhand tribals working under conditions that have been described as being close to slavery (Gadgil, 1942).

Elsewhere, these tribals were resettled in so-called forest villages. The primary focus of the plantations they worked on was to replace the natural sal-dominated, fairly diverse humid forest with monocultures of teak (*Tectona grandis*). Teak is excellent timber resistant to termite and fungal attacks, highly valued for ship building and gun carriages in the nineteenth and for furniture and house construction in the twentieth century. But teak is hard wood, little used traditionally; it also does not provide any other product of local utility. On the other hand, sal leaves are used to make plates and sal seed has value as an oil seed. Many associates of sal, such as mahua (*Madhuca indica*) and tendu (*Diospyros melanoxylon*) have great local utility. So replacement of natural sal forest by teak plantations deprives local people of access to a diversity of biological resources of value. Uprooted impoverished tribals have served over years as primary agents of such an erosion of biodiversity (Gadgil and Guha, 1995).

Transformations such as these are particularly common today in tropical developing countries, transformations that are actively encouraged by nation states as well as transnational development agencies as development efforts. These development efforts then have adverse impacts both on biodiversity and on the ability of the weaker sections of the population to access biodiversity. Indeed, they also have adverse impacts on the biodiversity conservation practices of the ecosystem people, practices such as protection to sacred plants and animals and sacred sites such as sacred groves and ponds.

Costs of Conservation

Conservation practices of the ecosystem people with their limited resource catchments are organized on limited spatial scales. Thus, the sacred groves have sizes ranging from a fraction of a hectare, to tens, at best hundreds of hectares. The biosphere people have their own conservation practices. In keeping with their larger resource catchments, they tend to protect much larger areas as nature reserves (Gadgil, 1996). Agrarian states had their tradition of hunting preserves of aristocracy, ranging in size from few hundreds to thousands of hectares. Such hunting preserves of nobles are described in Kautilya's Arthashastra, the 2000-year-old Indian manual of statescraft (Kangle, 1969). They are also known from medieval Asia and Europe. The hunting preserves were aimed at protecting major game animals such as lions or antelopes and their habitat for the entertainment of aristocracy. Their main focus was therefore on exclusion of access, especially to hunting in these areas, by all the commoners. In this, they would have tended to accentuate the poverty of people living within and adjacent to the hunting preserves.

The modern-day nature reserves are even larger in spatial scale, in keeping with the even larger resource catchments of modern-day societies of biosphere people. Thus the largest national parks of the day extend over hundreds of thousands of hectares. Many of them, as in India, have their roots in the hunting preserves of the aristocracy. Two notable examples of

these are the national parks at Gir, the last stronghold of the lion in India, and at Keoladev, Ghana, a wetland that shelters enormous nesting colonies of herons, storks, pelicans, and cormorants during monsoons and huge populations of migrating waterfowl in the winter. The focus at both these reserves is on exclusion of resource access by local peasants and herders, leading to major controversies.

At Gir (21°40' N lat. 70°30' E long.), the controversy centers on relocation of traditional colonies of buffalo keepers, the Maldharis outside the national park. Their free-ranging buffaloes were earlier an important prey for the lions, especially the males. On being located outside, the quality of grazing for the buffaloes has declined, and despite some reduction in the mortality of buffaloes from lions, the Maldharis are worse off. Within the national park the herbivore populations have increased with reduction of competition for grazing by buffaloes, but the lion population has not gone up. In fact, male lions continue to hunt Maldhari buffaloes who are now outside the limits of the national park. While Maldharis were earlier willing to accept some buffalo kills by lions as a compensation for access to grazing within the national park, they are no longer willing to do so. So they poison carcasses of buffaloes killed by lions; as a consequence the lions suffer (Johnsingh, pers. comm.).

In Keoladev national park (27°15' N lat. -77°35' E long.), famous for its water birds too, modern conservation attempts have involved exclusion of grazing in the extensive shallow wetlands. When grazing was thus banned in early 1980s without any alternatives being made available, there were protests leading to police firing, with some deaths. But the ban was implemented forcing local peasants to substantially reduce their livestock holdings, impoverishing them to a significant extent. But this cessation of grazing has also had an adverse impact on wetlands as a water bird habitat. This is because the wetlands have now become choked by an excessive growth of a grass, *Paspalum*. This particular conservation measure has thus tended to impoverish people as well as the bird life, which was at the center of the conservation concern (Vijayan, 1987).

Jharkhand tribals too have suffered from being excluded in the interest of nature conservation. One of the major recreation areas for the wealthy from Calcutta city is the Betla National Park (23°40' N lat. -84°40' E long.) in the Daltonganj district of Bihar. The tribals who were earlier settled in many forest villages in what now constitutes this national park are facing serious difficulties. With the constitution of the national park, the forestry operations employing them have been halted. Further restrictions are imposed on their collection of forest produce. Moreover, the tribals are now being asked to move out of the forest villages altogether, without any provisions for alternative livelihoods. So the tribals who were earlier instruments of destruction of biodiversity to help meet economic demands of the wealthy are now being further impoverished to meet their recreational demands for access to biodiversity (Gadgil, 1998).

Ecodevelopment

But there are other positive developments as well. The difficulties experienced by Jharkhand tribals have triggered a

variety of political protests, some non-violent, others violent. Among their demands is the creation of a separate Jharkhand state; since they see states of Bihar and West Bengal as being dominated by interests responsible for the political and economic subjugation of tribals. One of the slogans of this Jharkhand movement has an ecological content: Teak is Bihar, sal is Jharkhand. Their demand is for the retention of natural sal-dominated forest.

A notable development accompanying these protests is the program of participatory management of forest resources. Under this program villagers are encouraged to organize village forest committees (VFC) to promote natural regeneration of forests. The VFCs are given certain authority to control forests, an authority that was earlier monopolized by the Forest Department, and are expected to assume responsibility for forest protection. In return they are given full rights over non-timber forest produce such as sal leaves and oil seeds, as well as a share of any timber that may be harvested. This program, which was initiated in 1973 in the tribal villages of Midnapore district (22°20' N lat.–87°20' E long.) of West Bengal, has now spread over many other parts of this tribal belt, as well as elsewhere in the country. The program has by and large been a success. It is an important instance of the poor getting organized to promote ecological restoration, and in the process enhancing their own standard of living. Such ecological restoration also tends to enhance levels of biodiversity in conjunction with production of a variety of forest produce of value to local people (Poffenberger and McGean, 1996).

The Jharkhand political struggle also incorporates an issue with significant implications for biodiversity conservation. The tribal religious practices throughout the country included protection of sacred plants, animals, ponds, and forests, as was mentioned earlier in the Gangte case study. The system of sacred groves, called “saranas,” has been an important ingredient of the traditional tribal religion of Jharkhand. These saranas are variable in size—mostly small, about 0.1 ha—but very numerous and serve to protect samples of original natural plant life. These were treated with contempt by Christian missionaries who have a significant influence in this tribal region, as also by proponents of high-caste Hinduism. Now protection of these saranas has emerged as an element of the move to restore tribal self-respect and to empower them (Gokhale *et al.*, 1998). Indirectly then, conservation of indigenous biodiversity is beginning to emerge as a part of the agenda of the poor to pull themselves out of the poverty trap.

UNESCO's Biosphere Reserve program is another endeavor to combine efforts at conservation of biodiversity with alleviation of poverty. However, it has met with limited success largely because of inadequate understanding of local ecology and people's needs. Thus, Nandadevi (–30°30'–30°40' N lat. and 79°44'–79°58' E long.) in Western Himalayas is one of India's eight Biosphere Reserves. In this region, the traditional livelihoods depended on summer grazing in these pastures supplemented by collection of medicinal herbs. This grazing has been banned in the core zone of the biosphere reserve, along with mountaineering expeditions, another important source of cash incomes. As a result, local people feel significantly impoverished. The few ecodevelopment programs such

as fuelwood plantations that have been brought in as a part of the Biosphere Reserve activities have failed to create sufficient levels of additional incomes. At the same time local people believe that in the absence of grazing the diversity of medicinal herbs in the pastures are now being replaced by extensive growth of a few species such as *Rumex* (Negi, 1999).

The philosophy behind biosphere reserves, that of combining conservation with development efforts, also motivates a number of development programs that go by the name of “Integrated Conservation and Development Programs” (ICDP) and the many projects funded by Global Environment Facility (GEF). However, there has been little genuine progress so far in actually realizing these goals. As a review of a GEF program in New Guinea documents, the programs remain ineffective as they continue to be designed by outsiders committed to conservation but with little understanding of what would motivate local people, especially the poor, to participate in conservation efforts (Global Environment Facility, 1998).

There are also attempts to bring to local people financial benefits either through ecotourism or through sustainable harvesting of biodiversity resources. There are limited success stories of combining the two in parts of Zimbabwe where substantial incomes are generated though high-priced hunting licenses for large mammalian game animals, with levels of such harvests kept well within sustainable limits (McNeely, 1995). These incomes are shared with local, relatively poor people. Other attempts at combining poverty alleviation with biodiversity conservation have focused on promoting enterprises such as processing of medicinal plants or wild fruit. Programs in India involving processing of fruit of *Phyllanthus emblica*, a moist deciduous forest tree species by local Solliga tribals in B. R. hills of Karnataka or processing and marketing of wild mango by local women's groups in the Kangra district of Himachal Pradesh have met with varying degrees of success (Chopra, 1998). Providing alternative means of livelihood to communities depending on a threatened biological resource has also been attempted with success in the Indian ocean island of Seychelles where turtle shell artisans were provided financial and technical support to shift to occupations like coconut souvenir carving (Global Environment Facility, 1997).

The Challenge Ahead

Poverty thus relates to biodiversity in many, complex ways. But, by and large, the poor are today instruments of decimation of biodiversity in their attempts to earn livelihoods. There has been little success in addressing this problem through designing programs that would combine conservation and sustainable utilization of biodiversity with alleviation of poverty. This then is a major challenge that must be addressed in years to come.

Glossary

Economic rent Payment to resources in excess of costs.

Ecosystem services Contributions of ecosystem components through genetics, information, and reproduction.

Externality An effect – either a cost or a benefit – external to the generating activity.

Free rider One who enjoys the benefit of goods or service without paying the cost.

Institutions Organizational structures that shape human interactions.

Prisoner's dilemma Uncertainty about others' behavior leading to choices that are individually rational but collectively irrational.

Public goods Goods and services which if supplied to one person can be supplied to additional people at no extra cost.

Time horizon Time period over which future benefits and costs are considered.

Tragedy of the commons Overuse of resources resulting from open access and the incomplete accounting for costs.

Transactions costs Costs other than price associated with the trade of environmental goods and services: information, negotiation, decisions, and enforcement.

The Context of Property Rights

Property rights define the conditions that guide and control human use of the natural environment. They establish the terms under which people use and sustain the capacity of the environment to generate a continuing flow of goods and services. Property rights are a means by which people interact with their environment and control their behavior toward one another. They embody the expectations people have about natural resources and influence the way people make resource use decisions. Property rights link humans to each other and to natural systems through these expectations and decisions (Bromley, 1991; North, 1992; Schmid, 1995).

Scope

Property rights to natural resources control both use and conservation. Their scope may be individual species, genetic information contained in species, or areas of land and water in which species live. The scope of property rights also includes different types of use. At present, most systems of property rights are designed for direct uses, such as catching fish for food, but they may also include indirect uses, such as the right of the public to enjoy populations of whales or to protect endangered species like bald eagles. Property rights are almost never defined for unused species or for communities of species. The idea of using property rights for the protection of not only single species but also biodiversity and its genetic foundation is a newer and broader application of their accustomed use.

Values

If resources are used, they have value. The values of ecosystems that derive from direct uses are most easily recognized – for example, the harvest of shellfish and seaweed from intertidal marine ecosystems. Their value is expressed in markets or in the subsistence they provide. But indirect use also reflects

values that, although not well quantified, are important and well articulated as economic concepts. Resources have option values for the future as potential goods and services – for example, the future food or pharmaceutical uses of marine species. These potential uses are valued as insurance against the unknown. Resources also have quasi-option values in future uses that may exist through preservation or be lost by irreversible actions, such as the localized genetic information in subraces of salmon that are lost as habitat is destroyed. Finally, resources have existence values in their aesthetic or spiritual attributes, such as the enjoyment of watching an osprey catch a fish or the satisfaction of just knowing that ospreys are nesting nearby. Existence values can also be thought of as bequest values, in that the unused goods and services are available to be passed on to future generations.

An important contributor to the option value of ecosystems is ecological resilience. Resilience is the elasticity of the ecosystem; the ability of an ecosystem to absorb perturbations and continue its essential functions (Perrings *et al.*, 1995). Although much remains unknown about the necessary conditions for resilience, what is known is that there are keystone species that require protection and conservation to enhance both species diversity and critical ecosystem functions. The option values of direct uses of ecosystems are relatively easy to understand and measure, because they are linked to tangible goods like seafood and timber that are traded through markets. Considerable uncertainty exists, however, about the value of services or goods that are not currently used. Measuring and accounting for the option values of ecosystem services and unknown goods is difficult because there is no market in which people can express their willingness to pay for them or be compensated for their loss (Teab, 2010).

People and Biodiversity

Biodiversity can be viewed in a number of dimensions, including the diversity of species, the diversity of genetic material, and the diversity of functional roles in the ecosystem.

Many of the benefits of biodiversity are public goods, in which value accrues to everyone. The issue of people and biodiversity is one of managing the direct and indirect effects of activities in ecosystems in order to maintain the diversity of genetic, species, and functional components. One challenge is how to provide appropriate incentives so that people find it in their interest to promote and maintain the public good of biodiversity. A second challenge is how the rights, rules, and responsibilities that constrain resource use can be expanded from single species or physical areas to multiple species that may be distributed over wide areas. A third challenge is how to make the transition from traditional single-species commodity production types of use to new types of use that accommodate the protection of species diversity through the maintenance of ecosystem services.

Ownership

The idea of ownership is well understood for goods produced by ecosystems. Ownership is better defined for land-based resources than for marine resources but for both, the full range of property rights described in [Table 1](#) applies. Property rights to goods from land ecosystems are usually clearly defined and range from private to public. Property rights to goods from marine ecosystems are similarly mixed and often still include open access. Property rights to goods from marine ecosystems vary from private/community/state in nearshore areas, to state property in offshore zones, to open access in international waters.

The idea of owning ecosystem services, in contrast, is less familiar but is gaining in experimental application. At present, ecosystem services are either considered the property of the public or of the owner of the area in which they exist. Ecosystem services are public goods, but in neither land-based nor marine ecosystems are rights to services specifically defined. One particular ecosystem service – the genetic information embodied in species – is particularly important to the question of biodiversity. Property rights to the informational properties of resources are in only the very early stages of development and application ([Swanson, 2003](#)).

Forms of Property Rights

Property rights take many forms. Differences in form derive from the scope of the rights, the type of rights owner, and the privileges and responsibilities of the rights owner. The most common categories are private, public, state, and common ([Table 1](#)). The types of property rights are ordered loosely

along a spectrum, where the owner ranges from an individual person to no one ([Hanna et al., 1996](#)).

Open Access

Open access, *res nullius*, is the absence of property rights and has no ownership assigned. It is open to all, with resources becoming owned only at the point of capture. The absence of rights is often, but mistakenly, referred to as “common property.” The “tragedy of the commons” metaphor is a description of the outcome of open access. It describes the use of a common-pool resource from which it is too costly to exclude people from use. In the tragedy of the commons, individuals make choices about resource use based on their own private costs and benefits. And while the benefits of their actions accrue to them alone, the costs, in terms of the effect on the resource, are social costs spread among all users. Eventually and inevitably without some control over access, the failure to account for social costs locks people into behavior that leads to resource degradation and overuse ([Hardin, 1968](#); [Ciriacy-Wantrup and Bishop, 1975](#)).

Common Property

Although the “tragedy of the commons” is a metaphor that is widely used, it does not really describe common property. Common property, *res communes*, is owned by an identified group of people who have the right to exclude nonowners, the duty to participate in decisions about use, and the responsibility to act as resource stewards. For example, nearshore fishing territories may be owned and managed by the residents of the adjoining coastal community. Community members as owners decide how many people have rights to use the resource, what kind of rights these may be, and what objectives they have for resource productivity.

State Property

State property, *res publicae*, is owned by citizens who assign management authority and stewardship responsibility to an agency of the state. For example, U.S. fish and wildlife resources are the property of the citizens of individual states or of the country as a whole. The citizens designate the fish and wildlife agencies of individual states and the federal government to manage these resources in their name. The agencies may grant rights of use to individual users or communities of users, but the resources remain owned by the citizens at large.

Table 1 A classification of pure forms of property rights

Property rights	Rights holder	Privileges	Responsibilities
Open access	None	Capture	None
State property	Citizens	Designate management authority	Stewardship
Common property	Collective	Exclude nonmembers	Participation, maintenance
Private property	Individual	Socially acceptable uses; control of access; transfer	Compliance with laws

Private Property

Private property, *res privatae*, assigns ownership to named individuals including legal individuals, such as corporations, guaranteeing to those owners a bundle of rights about access and use. Although individuals have the greatest autonomy under private property, this form of property rights is also stunted by prohibitions against unacceptable uses, such as activities that pollute. For example, individuals may own land and the fish and wildlife on that land, but the types of use to which they can put either the land or the wildlife may be constrained by law.

Property Rights over Goods

The property rights listed in [Table 1](#) have one attribute in common: they have, in practice, been applied almost exclusively to environmental goods. We think of resources as natural capital that create value through the size of standing stock and through the flow of resources from that stock. We are familiar with property rights over the stock and flow components of natural capital. For example, in marine ecosystems rights can be assigned to the resource only on capture (competitive fishing), to the standing stock itself (territories for sedentary species), or to the flow of goods from the standing stock (individual fishing quotas). These are the tangible components of ecosystems.

Property Rights over Services

There are other intangible components of ecosystems that do not fall under these definitions of rights. For example, species provide services to the ecosystem and to humans through genetic information, reproduction, and contribution to critical ecosystem functions. Species and groups of species also provide additional value to humans through the genetic information they contain and the pleasure they provide. Property rights are poorly defined for ecosystem services such as genetic information. This is in spite of the fact that the idea of intellectual property rights over discoveries leading from information and ideas is a familiar one. Nations have patent and copyright systems that protect rights of ownership over goods and services that flow from the application of intellectual capital; these include designs, published works, and medicines. But the focus of intellectual property rights is on the discovery or creation that results from information, not on the information itself. The lack of systems of property rights for genetic information is a critical issue for its protection. The information stored in biodiversity could lead to discoveries and patented products, but for the potential investor, the necessary protections to encourage investment are not in place. Since rights to the use of genetic information are unspecified, incentives for its protection are also absent. Biodiversity is treated as an open access resource, with the familiar “tragedy of the commons” result. The coexistence of intellectual property rights and biodiversity protection has been an area of great controversy and the focus of international efforts to reconcile interests of the developing and developed states ([Kothari and Anuradha, 1999](#)).

Optimal Forms of Property Rights

Biodiversity is a public good at both national and international scales. Developing the means to protect its value is a critical challenge to property rights, and it is widely acknowledged that strengthening property rights over ecosystem goods and services is a necessary component of biodiversity protection. Some of the same conclusions that apply to property rights and the protection of single resources apply as well to multiple resources and biodiversity. The evidence of the applied property rights literature indicates that no single type of property rights can be a remedy for all needs of resource protection; the appropriate type depends on the resource management objectives and on the context. People often advocate a particular form of property rights as being best suited to manage and sustain natural resources. For example, arguments have been made for private property rights to natural resources to provide incentives for maintaining the flow of resource goods and services into the future. The idea is that private property rights would keep people from the “prisoner’s dilemma,” in which ignorance over the behavior of others leads to the collectively irrational outcome of resource overuse. The argument for universal private property ignores the differences in context in which they might be applied. It also disregards possibilities for cooperation and collective action that provide assurance about others’ behavior and that exist under other types of rights systems ([Ostrom, 1990](#); [Bromley, 1991](#); [Hanna et al., 1996](#)).

In recent years counter-arguments have arisen for the superiority of collective ownership over private ownership. These arguments are often framed in the context of community-based resource management. The idea behind this argument is that collective resource ownership and management is superior in terms of providing incentives for stewardship, providing collective access to resource benefits, and fairness in resource outcomes. Disputing each of these arguments for the superiority of a single type of property right is a large body of research that has demonstrated that there is no particular form of property right that is superior in all cases. Each type of property right – with the exception of open access, which is the absence of rights – can either succeed or fail in sustaining resources. What matters is how well the property right system fits within the ecological, economic, and social context and how well the form of the right reflects the type of use.

The fundamental problem for biodiversity protection is that much of the biodiversity value falls outside the realm of direct use. Direct uses are easiest to monitor and measure, control and trade. Indirect uses such as genetic information and aesthetic appreciation are less visible because their contribution is more diffuse over space and time. Because these resource values are seldom owned, bought, or sold, they are often at a competitive disadvantage in a market economy, leaving them undervalued and overused. This leads to the common approach of protecting biodiversity not through property rights but by removing them from human influence in sanctuaries, refuges, or reserves.

Functions of Property Rights

Property rights have several functions. They delineate the population of legitimate owners. They specify the allowable

actions of these owners and their associated responsibilities so that expectations are consistent and enforcement of rules is possible. And by setting consistent expectations they reduce uncertainty about others' behavior. In the larger sense, they connect the pieces of the natural system to the pieces of the human system. The basic functions of managing resources – coordinating users, enforcing rules, and adapting to changing environmental conditions – cannot be met without a system of property rights. The way that property rights function in any particular context determines whether the natural and human system will interact in compatible or conflicting ways (Hanna *et al.*, 1996). To be compatible with long-term biodiversity protection, systems of property rights must function in a way that deals with uncertainty, externalities, transactions costs, and scale.

Uncertainty

Uncertainty is endemic in natural systems. We lack knowledge about ecosystem structure and ecosystem condition. We often lack assurance about how others will behave, or we lack confidence about the future.

For example, there are large gaps in basic biodiversity knowledge; about threshold levels of protection, the measurement of ecosystem function, and the definition of biodiversity goals. In marine ecosystems relatively little is known about ecosystem composition, links between species, food, and reproductive requirements, critical ecological processes, and tradeoffs among species. These uncertainties affect the performance of property rights. Uncertainty about ecosystems may limit the ability to define goals and objectives for biodiversity. Uncertainty about the behavior of others will encourage intensified use to capture as many benefits as possible while they are available. Uncertainty about the future will shorten the time horizons over which decisions are made, removing the incentive to invest in long-term protection. All of these forms of uncertainty work against the protection of biodiversity.

In an uncertain environment, decision making takes place through trial and error. The uncertainty creates a natural tension between the individual and the group, and between people and ecosystems. Property rights address some, but not all, of the components of uncertainty. They define and sanction ownership, resolving the question of future access. They provide assurance about the behavior of others, because they define appropriate types of use. They do not in themselves increase knowledge about the ecosystem, although they may provide an incentive for owners of property rights to produce this information (Hanna, 1998).

Externalities

Another function of property rights is to resolve the problem of externalities, in which one action affects another. When property rights to resources do not exist or are incomplete, people do not take full account of the costs of their actions because there is no corresponding "owner" to lay counter claims. In open access fisheries, for example, people compete for resource benefits by fishing as fast as they can and catching

as much as they can. The result is that one person's behavior affects the amount of fish available to others over time, unless their rights are correspondingly protected. Similarly, destructive fishing practices can eventually affect the functioning of the ecosystem if rights to habitat or nonfished species are not in place. In some cases property rights may be defined but unenforceable, and the lack of enforcement then becomes equivalent to removing the right. For example, if fishing rights are expressed in terms of areas and people without rights are not excluded from those areas, their encroachment will render the right meaningless and externalities will continue.

The outcome of missing or unenforceable property rights is biodiversity loss, as only some components of the ecosystem are protected, leaving others vulnerable to external effects. The idea behind using property rights to protect biodiversity is to assign claimants to the full spectrum of ecosystem components and services, so that external effects are accounted for, or "internalized." If the owners of biodiversity are citizens, the state can then act in their behalf to protect biodiversity from various damages over space and time. The ability of the state to represent claims over biodiversity depends on a clear definition of the goods and services of ecosystems, an articulation of the relation between ecosystem components and ecosystem function, and an active constituency for protection (Perrings *et al.*, 1995; Sedjo and Simpson, 1995).

Transactions Costs

How well a system of property rights functions both affects and is affected by transactions costs. Transactions costs are the costs of doing business, which in the resource management context include costs of gathering information, coordinating users, organizing decision making, and enforcing rules. Some transactions costs remain fixed regardless of the type of process used to make decisions. Others vary with the way decisions are made – the amount of data collected, analyses done, and the process used to make decisions. Transactions costs are also influenced by the condition of the ecological system. As resources become depleted, a system of property rights must account for more and more externalities that increase the costs of management program design and enforcement. It is possible to create a system so costly to design or enforce that potential benefits are outweighed by the costs. This cost effect, particularly in consideration of actions to change property rights, is an important factor in the consideration of the transition to property rights for protecting biodiversity (Eggertsson, 1990; North, 1992).

Scale

The functioning of property rights is also affected by the scale of the area over which they apply. There is a disconnect between the geographic scale over which species are distributed and the scale at which species habitat is owned. Property rights to goods are relatively easy to define and enforce because they are associated with geographic space and their value is embodied in the goods themselves. But property rights to services are much more elusive. For example, rights to the information

value of species would involve several owners, even nations, over wide geographic space.

For rights to resources to have meaning in terms of providing incentives for their conservation, those rights must have value to the owners. The value rests in part on their uniqueness and exclusivity. When the resource is the genetic information encoded in a plant and the plant species is distributed over a range larger than that areas encompassed by the property right, the information embodied in that plant is also available to others, leaving the rights owner without the power to exclude or to capture the potential financial value from the information. This scale mismatch limits the potential for property rights to provide the appropriate incentives for investing in conserving the genetic information.

The scale question also means that biodiversity protection is often an international issue. There are global benefits to biodiversity that are unaccounted for in national systems of property rights. Species distributions are independent of national boundaries. In addition, the loss of biodiversity is often an international externality, where the impact of one nation's actions is felt by another (UNEP, 1992; Swanson, 1995).

Evolution of Property Rights

Property rights to resources tend to evolve incrementally over time in response to changes that alter the costs and benefits of particular forms. The current impetus for considering property rights for the protection of biodiversity is the scarcity resulting from declines in the number, range, and diversity of species that enhances biodiversity's value. The evolutionary path to this point, marked by a gradual expansion of property rights over ecological goods and services, is one that has reflected the relative changes in the benefits and costs of property rights as conditions of resource use change.

Single-Species Use

When resources exist in surplus to human needs, conservation actions are unnecessary and so rights, rules, and responsibilities have little meaning. In an environment of surplus, the costs of developing protective mechanisms exceed the benefits gained. As resource abundance declines, either from human pressures or natural events, the increasing scarcity raises the benefit of protection. When the benefits of protection exceed their costs, property rights in some form develop. The first controls are on how the resource is taken or how much is taken. For example, an open access, no-rules fishery becomes restricted by how people can fish – for example, by seasons or by limits on gear – and how many fish they can take. Eventually, property rights of access to the fishery are developed to restrict who can fish.

Ecosystem Use

As ecosystems are further exploited they reach a point where the focus on extracting and conserving individual species erodes the functioning of the ecosystem as a whole. Exploitation of species is interconnected, the sources of impacts are

diffuse, and effects of exploitation are system-wide. Species richness declines, community interactions are altered, and resilience erodes. It is at this point that the focus of managing human effects shifts from single species to ecosystems. This shift in focus takes place against a background of using resources for the production of goods: lumber from trees and seafood from fish. The rights, rules, and responsibilities are all directed toward this end. They are not designed to control effects on unused ecosystem components or to protect the flow of ecosystem services; the system of property rights is poorly adapted to these interactive effects.

Biodiversity decline creates scarcity in the services provided by species richness and genetic information. But the same scarcity in ecosystem services that provides an incentive to create property rights also presents a difficulty to developing ecosystem-level property rights. Ecosystem management is typically proposed when exploitation levels of single species are too high and showing signs of stress. Human competition and conflict over access to individual species complicate the shift to a broader focus and cause users to challenge the legitimacy of an ecosystem approach.

Expectations About Use

Property rights systems, once in place, create expectations about what is normal. They start in motion a new path of development. At each stage in the path, the condition of the resource, the definition of rights, and the expectations about those rights influence action. The further along the path the more embedded are the property rights and the more vested are people in their continuance. When faced with the necessity of expanding those rights to the protection of biodiversity, it must be done against the legacy of the path to this point. A property rights transition to the protection and conservation of biodiversity is affected by resource conditions at the intervention point. Protecting biodiversity means losing access to some of the goods and services of the ecosystem, which, under the old property rights rules, were at the disposal of the owner. Many resources have competing uses with known market values. Unknown future uses of these resources will be hard pressed to compete against known present uses.

Property Rights and Biodiversity Protection

A number of emerging issues illustrate the challenges to the use of property rights to protect biodiversity. Four are particularly relevant: uncertainty, exclusivity, distribution of benefits, and the alignment of private and social goals.

Uncertainty

Protecting biodiversity requires more than a set of rules and responsibilities for property rights set within institutions that accommodate the attributes of the ecosystem and the people who use it. How to design property rights and institutions for this accommodation is what is at issue. Although there is general understanding of the importance of biodiversity to the stability, function, and sustainability of ecosystems, there is

poor understanding of specifically what to protect. For example, knowledge is generally lacking of the thresholds at which biodiversity loss irreversibly changes ecosystems. Knowledge of the role played by individual species in contributing to critical ecosystem functions is also absent. These uncertainties create a corresponding uncertainty in the objectives and design of property rights to reflect the full range of values involved (Hanna, 1998).

Exclusivity

A problem with many property rights that apply to natural resources is that they do not specify claims to the full range of goods and services provided by an ecosystem. In failing to fully specify property rights claims, they fail to protect exclusive use. If property rights were defined for all components of an ecosystem, users and decision makers would take all the consequences of their actions into account. This would be the first step in making biodiversity conservation profitable. But under current systems of property rights, this is rarely the case. The history is to apply property rights to natural resources as commodities but not to the services they provide or to their existence value. The lack of full specification means that it is unclear who can claim and control rights of use.

Distribution of Benefits and Costs

How benefits and costs are distributed is the core debate of natural resource policy. The same debate is at the heart of biodiversity protection. Biodiversity values have the potential to be protected through a number of different types of property right. But whatever type of right is used will create winners and losers. It is difficult to design an effective system of property rights without addressing the distributional questions as well as questions of what the objectives are, how progress toward those objectives will be measured, and the time frame over which they will be met.

How to promote equitable distributions is a difficult question in all resource policy, but it is particularly so for the complex issue of biodiversity. Equity questions extend into the international arena, where the distribution of benefits between rich and poor nations is at stake. Those who receive the benefits of biodiversity protections may be distant interests, while those who incur the costs are local resource owners. Interest in protecting ecosystem services may exist among people outside a local area, but unless these interests coincide with the objectives of local owners, protection efforts are likely to be unsuccessful. Effective resource protection depends on legitimacy – on the acceptance of rules and procedures by participants. Many natural resource systems are difficult to monitor, and the possibilities for circumvention of rules are many. When people doubt the legitimacy of the system of property rights because they cannot accept its distributional outcomes, their incentives are to undermine rather than promote its evolution to a new form. Scarcity compounds the erosion of legitimacy by creating greater incentives and opportunity for rent seeking that is characteristic of resource competition.

Alignment of Private and Social Goals

For property rights to bring private preferences into line with public preferences for biodiversity conservation, the tensions between private and social goals must be resolved. Individuals have private goals for productivity of ecosystems goods that may not be compatible with social goals for biological production. Property rights can be an effective mechanism to create the appropriate incentives to conserve biodiversity, but the existence of property rights is not necessarily a sufficient condition for conservation. To promote biodiversity conservation property rights must be combined with resource management objectives that are consistent with conservation.

In addition, biodiversity is a public good, so it is subject to the potential for free riders to enjoy the benefits without paying the costs. Biodiversity protection must be accomplished in concert with existing rights and rules that favor direct uses of ecosystem goods. How to realign private and social incentives to conserve biodiversity is an important and to a large extent unresolved question. Most current systems of rights, because they are still unspecified for ecosystem services, favor the conversion of ecosystems into goods. Options for change include the expansion of the scope of property rights, payment of compensation to owners for conserving rather than using resources, or developing prohibitions against certain uses.

Conclusions

Property rights outline the conditions under which resources can be used and the interactions of people in using them. They exist in particular contexts that are combinations of ecosystems and people. There are many forms and permutations, none of which is superior to others. What determines the effectiveness of property rights in protecting biodiversity is the extent to which they are able to perform the functions of reducing uncertainty, removing externalities, containing transactions costs, accommodating scale and reflecting biodiversity goals.

Property rights evolve in response to external conditions. Scarcity is the driving force for their existence, and their contribution of benefits in excess of costs is the means of their continuance in a particular form. Despite the increasing scarcity of biodiversity, particular challenges face the evolution of systems of property rights to meet these conservation needs. To protect biodiversity, a transition must be made between current systems of rights that protect direct uses of ecosystems to expanded systems of rights that also protect indirect ecosystem services such as genetic information and aesthetic enjoyment.

The application of property rights to protect biodiversity is challenged by forces that are both internal and external to ecosystems. Internally, the increasing scarcity brought on by overexploited resources means that the range of options has declined. Fewer adaptations are possible. Formidable information needs for keystone species and critical functions of ecosystems exist. Both internally and externally, forces are competing to shape the time horizon of resource management. Biodiversity protection and notions of sustainable

use – values held by the public at large – are long-term concepts, requiring a long time horizon for management decision making. At the same time, the overexploited levels of many resources combined with uncertainty about their sustainability leads to internal pressures to shorten the time horizon and make decisions for the short run.

As these external and internal pressures illustrate, the very conditions in ecosystems that require biodiversity protection are also those which are causing difficulties in its implementation. Increased knowledge of ecosystems is needed as are innovative designs for property rights that work within and across national boundaries.

Glossary

Accounting prices Accounting or shadow prices are measures of the social opportunity cost of resource use. The accounting price of a resource is the increase in social well-being that would be enjoyed if a unit more of the resource was made available at no cost.

Ecological functions The combinations of ecosystem component and ecosystem processes that enable ecosystems to support primary production and to maintain populations of species.

Economic valuation The methods used to identify society's willingness to pay for the nonmarket benefits obtained from ecosystems.

Ecosystem processes Biogeochemical cycling, including primary production (photosynthesis), nutrient and water cycling, and materials decomposition, and the flow, storage,

and transformation of materials and energy through an ecosystem, including through food web processes such as pollination, predation, and parasitism.

Ecosystem services The benefits (i.e., goods and services) people obtain from ecosystems.

Production functions The combinations of capital stocks, material inputs, and technology to produce valued outputs.

Regulating services The benefits obtained from the regulation of ecosystem processes, including flood protection, climate regulation, human disease regulation, water purification, air quality maintenance, pollination, and pest control.

Resilience The capacity of an ecosystem to maintain functionality when subject to stress or shock.

Social discount rates The rate at which society is willing to substitute future consumption for present consumption.

Biological Resources and Biodiversity

Traditionally economists have approached the use people make of biodiversity through the individual species those people exploit: the fish that are caught in freshwater and marine capture fisheries; the trees that are harvested from either managed or natural forests; the livestock raised for meat, hides, and other animal products in pastoral systems; the food and cash crops produced in arable systems; or the medicinal plants extracted from forests, grasslands, and wetlands. To do this, they have relied on models of the growth of individual populations in which the functioning of the rest of the ecosystem is taken to be exogenous. Well known illustrations of this viewpoint include the use of the logistic function to chart the time path of the population of a single species of fish, the study of predator–prey interactions by means of variants of the Lotka–Volterra equations, the estimation of growth in biomass of a species of trees at a given site, and so on. A prominent concern has been to determine the rates at which a single resource would be harvested in different institutional settings. Thus, not only have socially optimum harvest rates been analyzed (Clark, 1976), but economists have also determined harvest rates when harvesters have free or open access to the resource (e.g., Gordon, 1954; Dasgupta, 1982).

This approach has given an understanding of the effect on harvest rates of harvesting costs, the rates at which harvesters discount future costs and benefits, the productivity of the resource *in situ*, the “worth” of the harvest to harvesters, and the property-rights regime in which the harvesting is done. It has also given an understanding of the implications of

changes in either the abundance or the intrinsic growth rates of exploited species. The approach has offered much less insight, however, into the economic effects of changes in the various measures of species richness (alpha, beta, or gamma diversity) or in the diversity within and between functional groups of species.

An alternative approach has focused on the ecosystem that is exploited when a particular species is harvested. In this approach, the resource switches from the individual species to the biotic and abiotic components of the system that regulate its growth. Instead of treating the role of the ecosystem as constant, as it is in the carrying capacity of a Lotka–Volterra population growth model, the approach allows investigation of the interactions between ecosystem components induced by human exploitation. There the focus is on system feedbacks through, for example, the energy flows involved in trophic interactions and the distribution and flows of biochemical substances in soils and water bodies, and of gases and particulates in the atmosphere. Where the state variables in the traditional approach are population “quantities” (e.g., herd sizes, expressed in numbers, or biomass units), in the ecosystem approach they may also include quality indices for air, soil, or water. The motivation is to understand the way in which the exploitation of ecosystems alters their usefulness to humankind by changing the biotic and abiotic processes that underlie various ecosystem functions, and hence the services they yield.

Economic studies of global warming, eutrophication of lakes, the management of rangelands, purification of water in watersheds, and the pollution of estuaries are examples of such endeavor (Mäler, 1974; Ludwig *et al.*, 2003; Perrings and Walker, 2005; Chichilnisky and Heal, 1998). Such studies have

provided valuable insights into the effects on ecosystems of the character of economic activities, as driven by technology, costs and revenues, discount rates, and the property-rights regime that governs access to the ecosystem. In this approach the focus of study is the ecosystem as a renewable natural resource system: a mix of functional groups of species that support a range of ecosystem processes, and hence a range of ecosystem services. Many ecosystems are deliberately “simplified” (through the removal of pests, pathogens, predators, or competitors) in order to increase their value for particular purposes. The best examples of this are to be found in agriculture, aquaculture, forestry, and urban systems. The biodiversity in such systems is managed to enhance production of particular services. But even the most simplified ecosystems – monocultures in agriculture and forestry and cities – are still ecosystems. The services they provide depend on the composition of species they contain, the energy and nutrient flows within the system, and the interactions between species.

This article asks how the second of these approaches informs the understanding of the value that biodiversity has to individual farmers, foresters, and fishers; how that differs from the value it has to wider society; and why the difference matters. All ecosystems generate an array of services that affect peoples’ well-being in different ways. All ecosystems are also subject to property rights or access rules that affect the rights and responsibilities of users, and that determine which services they take into account and which they do not. Biodiversity change is a problem for society if it has either significant social impacts that are ignored by users or unacceptable distributional consequences. This article considers both the inefficiency that results when biodiversity use involves external costs and the inequity that results when biodiversity change bears disproportionately on the poor.

Biodiversity and Ecosystem Services

The Millennium Ecosystem Assessment (MA) defined ecosystem services to include the full array of benefits people obtain from ecosystems distinguishing four broad benefit streams: the provisioning, cultural, regulating, and supporting services (Millennium Ecosystem Assessment, 2005). The MA provisioning services describe the processes that yield foods, fibers, fuels, water, biochemicals, medicines, pharmaceuticals, and genetic resources. Many of these products are subject to well-defined property rights and are priced in the market. Others are not. The MA cultural services comprise a set of largely non-consumptive uses of the environment including both the well-established market benefits of recreation and tourism and the spiritual, religious, esthetic, and inspirational well-being that people derive from the “natural” world, along with the value to science of the opportunity to study that world. The MA regulating services limit the effect of stresses and shocks to the system; include erosion control or soil stabilization, water purification, and waste treatment; and the regulation of air quality, climate, hydrological flows, pests, disease, and natural hazards. Finally, the MA supporting services comprise the ecosystem processes that underpin production of all these services, including soil formation, photosynthesis, primary production, nutrient, carbon, and water cycling.

The value of biodiversity derives from the value of the final goods and services it produces. To estimate this value, one needs to understand the “production functions” that link biodiversity, ecosystem functions, ecosystem services, and the goods and services that enter into final demand. Recent ecological research on the linkages between biodiversity and ecological functioning has improved the understanding of ecological processes involved in the production of a number of ecosystem services (Loreau *et al.*, 2002; Naeem *et al.*, 2009). It has also improved the understanding of the role played by the diversity of species in the production of these services. Species are related through functional traits that make them more or less perfect substitutes in executing particular ecological functions. Individual species near perfect functional substitutes for other species if they share a full set of traits with those other species. Conversely, they are “singular” if they possess a unique set of traits (Naeem, 1998). Species are also related through ecological interactions – trophic relationships, competition, parasitism, facilitation and so on – that make them more or less complementary in executing ecological functions (Thebault and Loreau, 2006).

The value of individual species depends both on their substitutability/complementarity in the functioning of ecological systems and on the way in that functioning has been affected by land use. The simplification of agroecosystems to privilege particular crops or livestock strains necessarily affects the array of services that system delivers, partly because the number of functions performed reduces with the number of species (Hector and Bagchi, 2007) and partly because each species in a system generally performs multiple functions. Ecosystems are systems of “joint production.” Individual systems generate multiple services. It follows that part of the cost of simplification is the ecosystem services foregone as a result. So, for example, modern agriculture has focused on increased yields per hectare, but has compromised a range of other ecosystem services including water supply, water quality, habitat provision, pollination, and soil erosion control (Millennium Ecosystem Assessment, 2005). It has also affected the capacity of the modified system to function over a range of environmental conditions – that is, its stability or resilience.

There is a vast and confusing literature on the relationship between diversity (or complexity) and stability or resilience (see, e.g., May, 1972; Pimm, 1984; Schulze and Mooney, 1993; Tilman *et al.*, 1996; Kinzig *et al.*, 2001), with many studies appearing to contradict each other. This is in part due to definitional ambiguities, in part due to analysis at different levels of organization, and in part due to differing results in theoretical versus experimental versus observational approaches. Most studies suggest that diversity (in the form of a greater number of species) enhances stability for community-level properties, though these results do not necessarily extend to the population level, where diversity can enhance, erode, or have little impact on stability (Tilman *et al.*, 1996; Mccann, 2000; Muradian, 2001). Most of these studies, though, address stability and resilience in a particular sense – how diversity affects the ability of a system to return to a previous (possibly equilibrium) state (Gunderson, 2000). They say less about resilience in the alternative sense (*sensu* Holling) – the contributions that diversity might play in diminishing the probability that a system might access entirely new system

configurations, or “flipping” into a new basin of attraction. (A system could be highly resilient in the second sense but not in the first – highly dynamic within a given basin of attraction, never returning to any given state for very long, but never leaving that basin of attraction, either.)

The relationship between diversity and resilience in this second sense is less clear. The vulnerability of low-diversity systems, such as agricultural monocultures, and the persistence of high-diversity systems, such as tropical forests, have often been cited as evidence of a relationship between diversity and resilience. Goodman (1975) takes these examples to task. In addition, there are equally compelling examples of low diversity systems that appear to be highly resilient – rice paddies have persisted in the same places for hundreds of years (Geertz, 1963; Lansing, 1991), and desertified and biologically depauperate regions are highly resistant to restoration efforts. (This latter example illustrates that resilience is not always a good thing.) These contradictions indicate the hazards of associating system-level properties with system-level outcomes. Degradation of soils, for instance, can cause both low diversity and high resilience, without there being a direct causal link between the two. Similar observations have been made about the role of productivity in high-diversity systems – are high-diversity systems productive, or are highly productive systems diverse?

Ecological theory suggests that increasing species number or complexity within a community should increase the number of equilibrium points or stable states (May, 1977; Deangelis and Goldstein, 1978). All else being equal, that would seem to imply more thresholds and lower resilience. Of course, all else would not be equal – it is entirely possible that increased diversity and complexity increase both the number of alternative states that can be accessed and the tenacity with which the system remains in any particular state. But both the theoretical and the empirical evidence for a strong relationship between diversity and resilience (*sensu* Holling), when correctly sorted, are still ambiguous.

Diversity can, of course, play a role in enhancing the functioning of ecosystems. More functional guilds will mean provisioning of a greater number of ecosystem services. Those services may or may not be resilient. What will enhance resilience (continued delivery) of a particular service is the diversity of species within the functional guild responsible for that service (e.g., within the guild of nitrogen fixers). If each species within a guild has a differential response to the environment, this would allow sustained function under environmental variability. This is known as functional redundancy.

Why should one necessarily expect species within a functional guild to have differential responses to the environment? Ecological theory suggests, in fact, that this is exactly what one should expect. In spite of perceptions of “nature red in tooth and claw,” evolution by natural selection, in fact, serves to diversify the niches of similar species and reduce competition among them (hence the diversification of beak sizes and shapes among the finches on the Galapagos Islands, each suited to different seed-gathering strategies). In most ecological communities it was also observed that just a few species make up the bulk of the biomass, with many more occurring in low abundance. The hypothesis is that both the breadth of services provided and their resilience are facili-

tated by these patterns. In particular, one might expect the dominant species to be functionally dissimilar (providing different services, but reducing direct competition through functional dissimilarity), with the lower-abundance species being functional redundants of the dominant species (but with different responses to environmental variability or stressors). Walker *et al.*, 1999 demonstrated just these outcomes in a grassland ecosystem subjected to grazing pressure. In the absence of grazing, dominant species were functionally dissimilar, whereas minor species were functionally similar to a dominant species. When dominant species declined or were eliminated by grazing, their functionally similar minor counterparts increased in abundance, thus maintaining certain functions within the disturbed grassland.

Although much remains to be done to understand the joint production of ecosystem services in particular ecosystems, the interactions between services, and the impact of changes in the relative abundance of species within and between functional groups, this article can now identify at least some of the consequences that biodiversity change for ancillary ecosystem services. The canonical bioeconomic models developed by Clark to understand the exploitation of marine mammals and fisheries (Clark and Munro, 1979) clarified the conditions required for the optimal extraction of particular populations, establishing the capital theoretical basis for exploiting biological stocks. The extension of such work to cover the exploitation of multiple species has made it possible to understand the effect of species interactions on co-produced ecosystem services (Tilman *et al.*, 2005; Eichner and Pethig, 2005; Brock and Xepapadeas, 2002; Perrings and Walker, 1997, 2005). This, in turn, has made it possible to track the physical effect of biodiversity change that lies outside the market, and to begin to estimate its social cost. This article first considers the generic issues involved in the diagnosis and cure of market failures, and then identifies their implications for the economics of biodiversity change.

Market Failure

A central concern among economists concerned with the environment has been to devise ways by which it would be possible to ascertain the “value” of natural resources and the services they provide. This is because for many natural resources and the services they support, markets simply do not exist. The interactions between biodiversity, ecological functioning, ecosystem services, and the production of the things that people care about most directly are not signaled by market prices. In some cases, markets do not exist because the costs of negotiation and monitoring are too high. One class of examples is provided by economic activities affected by ecological interactions involving long geographical distances (e.g., the effects of upland deforestation on downstream activities hundreds of miles away); another, by large temporal distances (e.g., the effect of carbon emission on climate in the distant future, in a world where forward markets are nonexistent because future generations are not present today to negotiate with the present generation). Then there are cases (e.g., the atmosphere and the open seas) where the nature of the resource makes private property rights impractical and so

keeps markets from existing; whereas in others, ill-specified or unprotected property rights prevent their existence, or make markets function wrongly even when they do exist. In short, market failures mean that people are not confronted by the real cost of their behavior (but *see* Market Failure). This gives rise to the phenomenon of externalities (i.e., exchanges among people that take place without their consent). (The early literature on ecological economics identified market failure as the underlying cause of environmental problems. (Pigou, 1920; Lindahl, 1958; Arrow, 1971; Meade, 1973; Mäler, 1974; Baumol and Oates, 1975; Dasgupta and Heal, 1979))

Problems arising from an absence of forward markets for “transactions” between the present generation and those to appear in the distant future are no doubt ameliorated by the fact that humans care about their children’s well-being and know that they, in turn, will care for theirs, in an inter-generational sequence. This means, by recursion, that even if people do not care directly about the well-being of their distant descendants, they do care about them indirectly. However, there is a distinct possibility that one’s implicit concern for the distant future via such recursion is inadequate, due, say, to institutional failure in other spheres of economic activity. This is why economists have argued that market rates of interest do not reflect socially desirable discount rates (Lind, 1982; Arrow *et al.*, 1996; Portney and Weyant, 1999). In short, market failure involves misallocation of resources not only in the present but also across time.

In each of these cases, the market prices of goods and services fail to reflect their social worth; typically, they are less than their social worth. In economics, the social worth of goods and services is called accounting prices (sometimes, shadow prices). The accounting price of a resource is the increase in social well-being that would be enjoyed if a unit more of the resource were made available at no cost. So a resource’s accounting price is the difference between its market price and the tax (or subsidy) that ought to be imposed on it. Needless to say, accounting prices reflect social objectives, ecological and technological constraints, and the extent to which resources are available.

It should be noted that externalities do not create market distortions; they are a form of market distortion. The presence of externalities leads to a wedge between market prices and accounting prices. Generally speaking, laissez-faire economies are not much good at producing publicly observable signals of environmental scarcities. To illustrate, if there were free access to a resource base, the market price of the resource, *in situ*, would be zero. However, if the resource were in limited supply, its accounting price would be positive. So, there is a directional bias in environmental externalities: market failure typically results in an excessive use of the natural resource base, not an insufficient one.

One way to improve matters would be to impose regulations on resource users, for example, restrictions on effluent discharges, quota on fish harvests, and bans on logging. Another would be to introduce a system of taxes, often called Pigovian taxes (in honor of Pigou, who first discussed the difference between private and social costs in the context of environmental pollution (Pigou, 1920)). Pollution charges, charges on the amount of fish harvested, and stumpage fees are examples. The idea underlying Pigovian taxes is to bring

market prices (inclusive of taxes) in line with accounting prices. Each of the two schemes, quotas and taxes, has its advantages and disadvantages, some of the differences between the two becoming salient once it is recognized not only that ecological processes are stochastic, but also resource users and government agencies do not have the same information about local ecology, say, for example, the cost of waste disposal (Weitzman, 1974; Dasgupta, 1982). This article cannot discuss this in details, but three points are worth noting. First, the two schemes are distributionally not equivalent: under a quota system resource rents are captured by harvesters and polluters, whereas under a tax system they are collected by the tax authority. Second, the imposition of Pigovian taxes provides greater incentives to resource users to explore resource-saving technological improvements. This is because if the users are taxed, they pay more for the resource than they would have if they had been issued quotas instead. Third, environmental taxes, when properly designed, remove market distortions. In addition, there is a presumption that tax revenues, thus collected, would enable the government to reduce distortionary taxes (e.g., taxes on earned income). There is, thus, a presumption that Pigovian taxes yield a “double dividend” (Bovenberg and Goulder, 1996; Goulder, 1995) (but see Bohm, 1996), a rhetorical phrase that has been much used to persuade governments to impose “green” taxes. Matters of public finance have been a recurrent theme in ecological economics since the 1970s (see, especially, Carraro and Siniscalco, 1996; Baumol and Oates, 1975; Cropper and Oates, 1992). A hybrid policy instrument, which involves the government issuing a fixed number of transferable licenses, combines some of the features of quotas and Pigovian taxes. For example, the scheme resembles quotas, in that, resource rents are not captured by government, and it resembles Pigovian taxes, in that at the margin license holders pay the accounting price of the resource for its use. (See Tietenberg (1990) for a good discussion of transferable licenses, both in theory and in practice.)

Institutional Failures and Poverty: Global Versus Local Environmental Problems

Aside from market failure, another long-recognized source of difficulty is what may be called government failure. For example, Binswanger argued that, in Brazil, the exemption from taxation of virtually all agricultural income (allied to the fact that logging was regarded as proof of land occupancy) provided strong incentives to the rich to acquire forest land and to then deforest it (Binswanger, 1991). He argued that the subsidy the government thereby provided to the private sector was so large, that a reduction in deforestation (via a removal of subsidies) was in Brazil’s interests, not merely in the interests of the rest of the world. That is, he concluded that Brazil had much to gain from reducing then current rates of deforestation. (In a wider discussion of the conversion of forests into ranches in the Amazon basin Schneider (1995) has demonstrated that the construction of roads through the forests has also been a potent force.) Since that time the government of Brazil has reached a similar conclusion. It has changed the incentives it offers to landowners and has entered into

negotiations with other countries that are potential beneficiaries of reduced deforestation in Brazil. At the heart of this decision is the recognition that there are interactions between ecosystem services generated by tropical forests. Land clearance for agriculture has consequences for biodiversity, water supplies, microclimatic regulation, and macroclimatic regulation (via carbon sequestration). Indeed, Brazil is now one of the main players in the development of the Reducing Emissions from Deforestation and Forest Degradation in Developing Countries (REDD) scheme. The scheme aims to create a financial value for the carbon stored in forests, offering incentives for developing countries to reduce emissions from forested lands (Malhi *et al.*, 2008; Phelps *et al.*, 2010; Arriagada and Perrings, 2011).

This said, it is important to note that the causes of environmental problems are not limited to market and government failure; problems also arise because such micro-institutions as the household can function badly. In poor communities, for example, men typically have the bulk of the political voice. One should then expect public investment in, say, resource regeneration to be guided by male preferences, not female needs. On matters of afforestation in the drylands, for instance, one should expect women to favor planting for fuelwood and men for fruit trees, because it is the women and children who collect fuelwood, whereas men control cash income (and fruit can be sold in the market). This explains why, even as the sources of fuelwood continue to recede, fruit trees are often planted (Dasgupta, 1993b).

That political instability (at the extreme, civil war) is a direct cause of resource degradation is obvious. What is not obvious is that it is a hidden cause as well. Political instability creates uncertainty in property rights. In its presence, people are reluctant to make the investments that are necessary for environmental protection and improvement: the expected returns on such forms of investment are low. In a study comprising 120 countries, Deacon has offered statistical evidence of a positive link between political instability and forest depletion (Deacon, 1994).

Taken together, these examples reflect the environmental consequences of institutional failure. They have a wide reach, and in recent years, they have often been discussed within the context of the thesis that environmental degradation, such as eroding soil, receding forests, and vanishing water supplies, is a cause of accentuated poverty among the rural poor in poor countries. There is truth in this. But there is also accumulated evidence that poverty itself can be a cause of environmental degradation (Dasgupta, 1993a, 2001). This reverse causality occurs because some natural resources (e.g., ponds and rivers) are essential for survival in normal times, whereas others (e.g., forest products) are also a source of supplementary income in times of acute economic stress. Under changing circumstances (e.g., economic development in urban centers), social norms that previously had maintained long-term economic relationships among members of a community tend to break down. Some (e.g., the able bodied and mobile) gain, whereas others (e.g., women, the old, and the very young) lose and become poorer. In extreme cases the breakdown of social norms also means that local resources that earlier were subject to communitarian regulations become "open access," with all the attendant consequences.

These links between rural poverty and the state of the local natural resource base in poor countries offer a possible pathway along which poverty, resource degradation, and even high fertility feed on one another in a synergistic manner over time (Dasgupta, 1993a, 1995, 2000). Experience in sub-Saharan Africa and Pakistan is not inconsistent with this (Cleaver and Schreiber, 1994; Filmer and Pritchett, 1996). Indeed, an erosion of the local natural-resource base can make certain categories of people destitute even while the economy's gross national product (GNP) increases. The thought that entire populations can always be relied upon to make the shift from resource-based, subsistence existence to a high-income, industrial one is belied both by evidence and by theory.

These two causes of resource degradation, namely, institutional failure and poverty, pull in different directions and are together not unrelated to an intellectual tension between the concerns people share about global warming and acid rain, which sweep across regions, nations and continents, and those matters (such as, for e.g., the decline in firewood or water sources) which are specific to the needs and concerns of the poor in as small a group as a village community. Environmental problems present themselves differently to different people. In part, it is a reflection of the tension this article has just noted and is a source of misunderstanding of people's attitudes. Some people, for example, identify environmental problems with poverty and unprecedented population growth in the South, whereas others identify them with wealth and unprecedented expenditure patterns in the North. Even though debates between the two groups often become shrill, each vision is in part correct. There is no single environmental problem and, so, no single valuation problem; rather, there is a large collection of them. Thus, growth in industrial waste and resource use has been allied to increased economic activity; in the former Socialist bloc neither preventive nor curative measures have kept pace with the production of waste. Moreover, the scale of the human enterprise, both by virtue of unprecedented increases in the size of the world's population and by the extent of economic activity, has so stretched the capabilities of ecosystems that humankind can today rightly be characterized as Earth's dominant species (Vitousek *et al.*, 1997). These observations loom large not only in ecological economics, but also in the more general writings of environmentalists and in the professional writings of ecologists in the West.

However, economic growth itself has brought with it improvements in the quality of a number of natural resources. The large-scale availability of potable water, and the increased protection of human populations against both water- and air-borne diseases in industrial countries, have in great measure come in the wake of growth in national income these countries have enjoyed over the past 200 years or so. Moreover, the physical environment inside the home has improved beyond measure with economic growth. For example, cooking in South Asia continues to be a central route to respiratory illnesses among women. Such positive links between economic growth and environmental quality often go unnoticed by environmentalists in the North. This lacuna may be yet another reflection of the fact that it is all too easy to overlook the enormous heterogeneity of Earth's natural resource base, ranging as it does from the atmosphere, oceans, and

landscapes to water holes, grazing fields, and sources of fuel-wood. Both this heterogeneity and the diversity of the human condition across the globe constantly need to be kept in mind in discussions of the value of biodiversity in different locations.

Valuing Resources and Evaluating Projects

Since institutional failures abound in human dealings with Earth, the commercial profitability of economic activities, say, of investment projects (projects for short), is frequently not an adequate measure of their social worth. So recourse should be taken to social cost-benefit analysis, the purpose of which is to estimate the impact of projects on human well-being, now and in the future. Notice that, if undertaken, a project would be a perturbation to the economy. So, for example, a project consisting of the construction of a dam would be a perturbation to an economy without the dam. The economic forecast *sans* the project can be thought of as the *status quo*.

Analyzing the consequences of a project would involve estimating the need for labor, intermediate products, raw materials, and output, as well as predicting the ecological effects of the project. These consequences need to be specified for each future period (*see* Discontinuous Value Functions for a formalization). Since there is never sufficient knowledge to make precise estimates of the consequences, project evaluators should quantify estimates of the uncertainties, preferably in terms of probabilities. This means that, in general, project designers ought to model the integrated ecological and economic system. Unhappily, in practice this is infrequently done.

To arrive at a good estimate of a project's social benefits and costs, one should in principle value each and every commodity involved in it. The procedure devised by economists is to select some readily measurable bundle of goods ordinarily consumed and to define the "value" of any other commodity as the amount of the bundle society would be willing to give up for it. This is a workable way for estimating the commodity's accounting price. The net social benefit of a project in any given period of its life is obtained by multiplying the project's inputs and outputs in that period by their corresponding accounting prices and adding them (outputs of "goods" are taken to be positive; output of "bads" and inputs are taken to be negative). Using a suitable discount rate (often called the social discount rate), the net social benefits yielded by a project in each period are added. Projects that yield a positive present discounted value of net social benefits are recommended for acceptance; those that yield a negative present discounted value of net social benefits are rejected. The theory of social cost-benefit analysis has been developed by economists over the past 50 years, and is now, to all intents and purposes, complete (Dasgupta *et al.*, 1972; Little and Mirrlees, 1974; Dasgupta and Mäler, 2000). Daily *et al.* (1999) provides a nontechnical account of the role of social cost-benefit analysis in environmental management.

A prior exercise (i.e., prior to conducting social cost-benefit analysis) is to estimate accounting prices. A great deal of work in ecological economics has been directed at discovering methods for estimating accounting prices of natural resources.

It is as well to remember that the kinds of resources this article mentions are on occasion of direct use in consumption (as with fisheries), on occasion indirectly, as inputs in production (as with plankton, which serves as food for fish), and sometimes in both (as with drinking and irrigation water). The value may be utilitarian (e.g., as a source of food, or as a keystone species), it may be esthetic (e.g., a shoreline), or it may be intrinsic; indeed, it may be all these things.

Economists have devised various methods for estimating accounting prices. As would be expected, the prices of some natural resources are easier to estimate than those of others. There are now standard techniques for determining the accounting prices of irrigation water, fisheries, timber, and agricultural soil (Anderson, 1987; Repetto *et al.*, 1989; Solorzano *et al.*, 1991; Vincent and Ali, 1997). They involve estimating the resource's use-value. For example, the value of a piece of agricultural land would be the present discounted value of the flow of net profits it is expected to generate from cultivation, minus the environmental damage caused by the pesticides and herbicides to be used. Such an approach can be also used for estimating losses associated with water logging and overgrazing. Reductions in air- or water-borne pollution can be valued in terms of improvements in health (e.g., reductions in the number of days people would be expected to be ill; *see, e.g.,* (World Bank, 1992)). Other techniques have been devised for valuing "amenities," such as places of scenic beauty. One popular method involves asking people hypothetical questions concerning their willingness to pay for preserving the amenity (this is called the "contingent-valuation method," or CVM, for short); another involves estimating from sample surveys the distribution of costs visitors from different locations have incurred to view the site (this is called the "travel-cost method"). A third involves inferring how much people are willing to pay for enjoying the amenity (e.g., clean air) from the commercial value of land at sites that offer the amenity (this is called the "hedonic price" of land). (*See* Mitchell and Carson, (1989) and Freeman (2003).) Good descriptions of these methods and their application to valuing ecosystem services can be found in Freeman (2003).

Two things that complicate the valuation of biodiversity change are uncertainty in the future use-values of these resources and irreversibility when they are lost. The twin presence of uncertainty and irreversibility implies that preservation of the stock has a value in addition to its current use-value, namely, the value of extending society's set of future options. (For a review of the challenges posed by these two issues, *see* Perrings and Brock (2009).) Future options have an additional worth because with the passage of time, more information is expected to be forthcoming about the resource's use-value. This additional worth is often called an option value (Arrow and Fisher, 1974; Henry, 1974; Fisher and Hanemann, 1986). The accounting price of a resource is, at the very least, the sum of its direct use-value and its option value.

These techniques enable one to estimate the use-value of a given resource. As it happens, the resource's accounting price may well exceed this. Why? The reason is that there may be additional values "embodied" in a species, an assemblage of species, or a landscape. This is sometimes captured in the idea that living resources have an "intrinsic" worth as living resources. It would be absurd to suppose that the value of a blue

whale is embodied entirely in its flesh and oil or that the value of game in Kenyan safari parks is simply the present-discounted value of the flow of tourists' willingness-to-pay to view them. The idea of intrinsic worth of living things is inherent not only in traditional religious systems of ethics but also in modern ethical theories. Economists tend to think of this as the nonuse value of resources. The question is not so much whether living creatures have nonuse value (intrinsic worth), but rather of ways of assessing this worth. Since it is very difficult to get a quantitative handle on intrinsic worth, the correct thing to do may often be to take note of it, keep an eye on it, and call attention to it in public debate if the stock is threatened with destruction.

It can be concluded that the social worth of natural resources can be decomposed into three parts: their use value, their option value, and their nonuse value. The components appear in different proportions, depending on the resource. For example, oil and natural gas would not be thought to have very low nonuse value relative to their use value. In contrast, endangered primates would be thought to have very limited use value relative to their nonuse value. And so on.

For both use and nonuse values, wherever species are identified in the functions that describe ecosystem processes and functions, one can also identify their marginal impact on the output of things people care about. The marginal value of an incremental change in the abundance of any species derives from the value of the services it yields. Derivation of that value requires specification of the functions that connect species to directly valued goods or services (Barbier, 2007) or that connect ecosystems and the services they produce (Barbier, 2008). Whether one uses market prices or revealed or stated preference methods to obtain an estimate of willingness to pay for the directly valued goods or services is more or less irrelevant. What is important is that some form of "production function" approach is needed to estimate the value of a marginal change in the biodiversity that supports the directly valued good or service. A good example of the combination of methods is Allen and Loomis, (2006). They combine willingness-to-pay estimates obtained using stated preference methods for the conservation of directly valued higher-trophic-level species with ecological data on trophic relationships to derive estimates of implicit willingness to pay for the conservation of species lower down the food chain.

It is as well to emphasize that the purpose of estimating environmental accounting prices is not to value the entire environment; rather, it is to evaluate the benefits and costs associated with changes made to the environment due to human activities. Prices, whether actual or accounting, have significance only when there are potential exchanges from which choices have to be made (e.g., when one has to choose among alternative investment projects). Thus, the statement that a particular act of investment can be expected to degrade the environment by, say, 1 million dollars annually has meaning, because it says, among other things, that if the investment were not to be undertaken, humanity would enjoy an additional 1 million dollars of annual benefits in the form of environmental services. The statement also has operational significance: the estimate could (and should) be used for calculating the rate of return attributable to the investment in question.

Biodiversity: Necessity or Luxury?

The starting point is that the value of biodiversity derives from its role in the production of things that people care about. This extends from clean water, through the production of foods, fuels, fibers, and pharmaceuticals, all the way to the spiritual, cultural, or scientific value of intact ecosystems or totemic species. It follows that the value people implicitly place on biodiversity change depends on the value of the ecosystem services they want. For those who are most directly threatened by pests or diseases, the most important consideration may be pest or pathogen elimination. For those engaged in the production of foods, fuels, or fibers, the most important consideration may be the elimination of crop predators (e.g., insect pests), competitors (e.g., weed species), and diseases (e.g., blights and rusts). For those engaged in conservation or ecotourism the most important consideration may be the preservation of native species and the elimination of exotic species. For those engaged in managing the impacts of trade or travel, the most important consideration might be preventing movement of potentially invasive plants, insects, or diseases. Since the services that people care about are likely to differ depending on geographical location, culture, income, and so on, the value they attach to changes in biodiversity is also likely to differ. And since many services are increased by focusing on a relatively small number of species, people may be expected to put a positive value on reducing species richness as often as they put a positive value on enhancing it.

This helps putting into perspective the common view that the rich value biodiversity more than the poor: that biodiversity conservation is a "luxury" good. The natural resource base is far from being a luxury. As the source of a multitude of ecosystem services necessary to the lives and livelihoods of the majority of people on the planet, the natural-resource base is a necessity. The way that the poorest of people depend on the resource base may differ from the way that the rich do so, but both do depend on it. (The way that the poor depend on the resource base is explored in greater detail in Dasgupta (2001, 1993a) and Dasgupta and Mäler (1997).

This perspective, of viewing natural resources as luxuries, first found expression in World Bank (1992), where it was suggested that there is an empirical relationship between gross domestic product (GDP) per head and concentrations of industrial pollutants. Based on the historical experience of OECD countries, it was argued in the document that when GDP per head is low, concentrations of atmospheric pollutants (e.g., sulfur dioxide (SO₂)) increase as GDP per head increases, but when GDP per head is high, concentrations decrease as GDP per head increases further. In short, it was found that the functional relationship between GDP per head and concentrations of industrial pollutants has an inverted-U shape (Figure 1). Among economists this relationship has been christened the "environmental Kuznets curve." (It is a misnomer. The original Kuznets curve, which was an inverted U, related income inequality to real national income per head on the basis of historical cross-country evidence.)

Panayotou had reported the inverted-U shape in cross-country data on GDP per head and deforestation and emissions of SO₂, nitrogen oxides (NO_x), and particulate matters (Panayotou, 1992). The logic underlying the environmental

Figure 1 Urban concentrations of sulfur dioxide. Reprinted from figure 4 in *World Development Report* (1992), with permission from World Bank.

Kuznets curve is that resource degradation is reversible: degrade all you want now, you can always recover the stock later, because Earth can be relied upon to rejuvenate it. It is known, however, that this presumption does not apply to biodiversity loss. The presence of ecological thresholds implies that damage to ecosystems can be irreversible. As an overarching metaphor for “trade-offs” between manufactured wealth and resource degradation, the environmental Kuznets curve has to be rejected. (For more extensive discussions of the environmental Kuznets curve, see Arrow *et al.* (1995), and the responses it elicited in symposia built round the article in *Ecological Economics*, 1995, 15(1); *Ecological Applications*, 1996, 6(1); and *Environment and Development Economics*, 1996, 1(1); and see the special issue of *Environment and Development*, 1997, 2(4).)

The relation between income and biodiversity loss has been approached in three ways in this literature. In one approach, deforestation has been used as a proxy for biodiversity loss (using the species area relationship to explain the link between changes in forest area and biodiversity loss). The evidence for any well-defined relation between income and biodiversity loss using this metric is extremely weak (Dietz and Adger, 2003; Mills and Waite, 2009). A second approach uses the National Biodiversity Risk Assessment Index (NABRAI) developed by Reyers *et al.* (1998). This too has failed to find evidence for a statistically significant relation between biodiversity loss and income (Mozumder *et al.*, 2006). A third approach has focused on the direct measures of threat contained in the IUCN’s Red List, and finds a statistically significant relation between the natural log of *per capita* income and the number of threatened species that is linear in the case of plants; “U” shaped in the case of amphibians, reptiles, fishes and invertebrates, and inverted “U” shaped in the case of birds (Naidoo and Adamowicz, 2001). More recently, Perrings and Halkos have reconsidered this latter approach using the most recent IUCN data. Controlling for climate, population density and protected areas, they find a strongly quadratic relation between *per capita* Gross National Income and the number of threatened species. They conclude that the interest people have in the abundance of other species is indeed sensitive to income. In poor countries where agriculture is expanding most rapidly at the extensive margin (by bringing new land into cultivation), people have a direct interest in habitat conversion, and in the elimination of weeds, pests and predators. They may also have an interest in conserving their biological heritage, and many poor countries have committed

a significant share of their total land area as protected areas, but their willingness to pay for conservation is strictly limited by their income – their ability to pay (Perrings and Halkos, 2010).

Substitution Possibilities

This section and the following one are based on Dasgupta *et al.* (2000a, b) and Dasgupta and Maler (2004). In fact the belief that constraints arising from resource depletion can be overcome as countries become wealthier in terms of their manufactured- and human-capital assets is frequently based on a subtler thought than the one that underlies the environmental Kuznets curve. The belief is based on possibilities of substitution.

Resource constraints facing an economy can be eased by four types of substitution. First, there can be substitution of one thing for another in consumption (nylon and rayon cloth substituting for cotton and wool, pulses substituting for meat, and so forth). Second, manufactured capital can substitute for labor and natural resources in production (the wheel and double-glazing are two extreme examples). Third, novel production techniques can substitute for old ones. For example, the discovery of effective ways to replace the piston by the steam turbine (i.e., converting from reciprocating to rotary motion) was introduced into power plants and ships a little more than a hundred years ago. The innovation was an enormous energy saver in engines. Fourth, and for this article most importantly, natural resources themselves can substitute for one another. This involves the thought that, as each resource (e.g., each species) is depleted, there are close substitutes lying in wait, either at the same site or elsewhere. If this were true, then even as constraints increasingly bite on any one resource base, humanity would be able move to other resource bases, either at the same site or elsewhere. The enormous additions to the sources of industrial energy that have been realized (successively human and animal power, wind, timber, coal, oil and natural gas, and most recently, nuclear) are a prime historical illustration of this possibility. (But these shifts have not been without unanticipated collective costs. Global warming, associated with the burning of fossil fuels (an “externality”), did not feature in economic computations in earlier decades. (See Dasgupta (1993b) for a less coarse partition of substitution possibilities than the four-way classification.)

Humans have been “substituting” one thing for another since time immemorial. Even the conversion of forests into agricultural land in England in the middle ages was a form of substitution: large ecosystems were transformed to produce more food. However, the pace and scale of substitution in recent centuries have been unprecedented. Landes has argued that substitution made the Industrial Revolution in England in the eighteenth century (Landes, 1998). The extraordinary economic progress experienced in Western Europe and North America since then (during the past two centuries GDP per head in Western Europe has increased some twelve-fold), and in East Asia more recently, has also been a consequence of substitution. Spatial dispersion of ecosystems has enabled this to happen. The ecological transformation of rural England in

the middle ages presumably reduced the nation's biodiversity, but it increased income without any direct effect on global productivity.

But that was then and this article discusses the here and now. A question currently much debated is whether it is possible for the scale of human activity to be increased substantially beyond what it is today, without placing undue stress on the major ecosystems that remain. In any event, the cost of substituting manufactured capital for natural resources can be high. Low-cost substitutes could turn out to be not so low cost if accounting prices were used in the costing, not market prices. Even when accounting prices are not used, degrading natural capital and substituting it with manufactured capital can be uneconomic. Studies of the well-known Catskill Watershed ecosystem in New York State demonstrated the overwhelming economic advantages of conservation of the watershed over construction of water-purification plants. Chichilnisky and Heal, for example, showed that independent of the other services the Catskill Watershed provides, and ignoring the annual running costs of 300 million US dollars for a filtration plant, the capital costs alone showed a more than six-fold advantage for investing in the natural-capital base (Chichilnisky and Heal, 1998).

Degradation of a natural-resource base (e.g., destruction of native populations of flora and fauna) not only affects the volume and quality of ecosystem services the base provides, but it also challenges the system's resilience, which is its capacity to absorb disturbances, or perturbations, without undergoing fundamental changes in its functional characteristics. The way to interpret an ecosystem's loss of resilience is to view it as having moved to a new stability domain, which is another way of saying that the system, having crossed a "threshold," has been captured by a different attractor (Levin *et al.*, 1998; Levin, 1999; Brock *et al.*, 1999). Sudden changes in the character of shallow lakes (e.g., from clear to eutrophied water), owing to increases in the input of nutrients (Scheffer and Carpenter, 2003) and the transformation of grasslands into shrublands, consequent upon nonadaptive cattle-management practices (Perrings and Walker, 2004) provide two examples. Human societies have on occasions been unable to avoid suffering from unexpected flips in their local ecosystems because of this.

In particular ecosystems, biodiversity has been shown to be key to ecosystem resilience. However, even today it is a popular belief that the utilitarian value of biodiversity is located mainly in the potential uses of genetic material (e.g., for pharmaceutical purposes), or in other words, that its social worth is almost wholly an option value. Preservation of biodiversity is seen as a way to hold a diverse portfolio of assets with uncertain payoff. But as other contributions to this Encyclopedia make clear, biodiversity, appropriately conceived, is essential for the maintenance of a wide variety of services on which humans depend for survival. This has the important corollary that to invoke the idea of substitutability among natural resources in order to play down the use value of biodiversity, as has often been done (Simon, 1981), is a wrong intellectual move. The point is this: if an ecosystem's biodiversity is necessary for it to be able to continue providing humans with its services, the importance of that same biodiversity cannot be downplayed by the mere hope that for

every species, there are substitute species lying in wait within that same ecosystem. In short, there is an inconsistency in this line of reasoning. Recall Ehrlich and Ehrlich's famous analogy relating species in an ecosystem to rivets in an airplane (Ehrlich and Ehrlich, 1981). One by one, perhaps, species may disappear and may not be missed. Eventually, however, the cumulative effect of loss of biodiversity will lead to the crash of ecosystem functioning, just as the cumulative loss of redundant rivets will lead to the crash of an airplane.

Discontinuous Value Functions

How do discontinuities in the social worth of ecosystems affect valuation exercises and social cost-benefit analysis? To answer this, it helps to formalize.

Consider an ecosystem describable by N state variables, indexed by i and j ($i, j = 1, 2, \dots, N$). For concreteness, one may think of each state variable as reflecting the population size of a particular species. (As noted in the section Biological Resources and Biodiversity, problems of environmental pollution can be formulated in a similar manner.) Denote time by t (≥ 0) and let S_{it} be the population size of i at t . Time is taken to be a continuous variable. Imagine, therefore, that the dynamics of the ecosystem can be described by a system of (nonlinear) differential equations. For expositional ease, one can assume for the moment that the system is deterministic.

Let the net reproduction rate of i at t be F_{it} . Since the ecosystem is coupled, F_{it} is a function of the stocks at t . This can be written as $F_{it}(S_{1t}, S_{2t}, \dots, S_{Nt})$, for $i = 1, 2, \dots, N$. It is assumed that ecologists have estimated these functions. Assume next that the ecosystem dynamics are autonomous. This means that F_{it} is not an explicit function of t . So drop the subscript t from F_{it} and write the function as $F_i(S_{1t}, S_{2t}, \dots, S_{Nt})$. In all the familiar applications of this framework with which we are familiar, F_i is taken to be a differentiable function. Assume this.

The analysis begins at $t=0$ (the "present"). Denote by X_{it} the rate at which species i is harvested at time t . Now imagine that economists have studied the human-ecosystem interactions in question. They have enquired into the structure of property rights, demand conditions, government policies, and so forth. On the basis of this they have concluded that harvests are based on an implicit policy, in that they are time autonomous and are functions solely of stocks. So one may write $X_{it} = X_i(S_{1t}, S_{2t}, \dots, S_{Nt})$. Assume that X_i is piece-wise continuous and possesses right- and left-partial derivatives everywhere. This is a technical assumption and a good one. For example, optimal policy functions for those ecosystem management problems that have been studied have been found to possess this property (Skiba, 1978; Brock *et al.*, 1999). Moreover, actual harvest rates have frequently been known to be approximately constant over time. So both sets of example satisfy the assumption. (Actual harvest rates frequently display time trends, say, because population and income grow. Time trends in X_{it} would render the system of eqn [1] non-autonomous. This article restricts the discussion to autonomous systems because it is understood that the mathematics of autonomous system is better than that of nonautonomous ones. But experience with simple nonautonomous systems

suggests that the arguments offered next cover them as well.) No doubt some of the X_{it} s would be zero. For example, it could be that only one species in the ecosystem is ever harvested (because, say, it is the only one that has economic worth). One should think of X_{it} as a forecast. It should be stressed that $X_i(S_{1t}, S_{2t}, \dots, S_{Nt})$ is not necessarily a socially optimal harvest-policy function. It can be an actual policy function within an imperfect institution (e.g., the ecosystem could be one to which there is free access).

The rate of increase of S_{it} is the difference between F_i and X_{it} . Therefore, given the economists' forecast for X_{it} , mathematicians would be able to forecast S_{it} by solving the "coupled" system of differential equations:

$$dS_{it}/dt = F_i(S_{1t}, S_{2t}, \dots, S_{Nt}) - X_i(S_{1t}, S_{2t}, \dots, S_{Nt}), \quad \text{for all } i \quad [1]$$

For simplicity of exposition, assume that the social worth of the ecosystem is autonomous in time. Then express that worth by a scalar V . Since V would be a function of the stocks, and may be written as $V(S_{1t}, S_{2t}, \dots, S_{Nt})$. V is the value at t of the entire ecosystem. It is the maximum amount society should be "willing to pay" at t for the ecosystem's survival if the stocks of the N resources were $S_{1t}, S_{2t}, \dots$, and S_{Nt} respectively. Any alternative use of the site (e.g., conversion into an urban center) would have to be worth at least V if the alternative were to be acceptable. The form of V would depend on the availability of substitutes for those species that are harvested. Again, to keep the mathematical notation from getting out of hand, assume that there are no substitutes available at low cost from outside the ecosystem (e.g., because the community doing the harvesting is not near other sources of livelihood). From eqn [1] it is possible to use the forecast on harvest rates to determine forecasts on stocks. This in turn makes it possible to forecast the time path of V .

At one level the valuation problem is now "solved": $V(S_{1t}, S_{2t}, \dots, S_{Nt})$ would be the value of the ecosystem at t . It would be the social worth of the ecosystem at t . The problem is that V is typically a nonlinear function, which means that it is hugely difficult to estimate. The task of valuing ecosystems would be made much easier if recourse were taken to estimating accounting prices. The advantage would be this: since accounting prices reflect the social worth of marginal units of the various populations, one could use such prices to construct a linear index of the ecosystem's value. This article turns to this discussion.

Assume for the moment that V is differentiable everywhere. Let P_{it} be the accounting price of i at t . From the discussion in the section Institutional Failures and Poverty: Global versus Local Environmental Problems and from the assumption that no substitute resources are near in hand for the human community in question, it is known that (if substitutes were available, P_{it} would be the minimum of $\partial V / \partial S_{it}$ and the accounting price of the substitute. It is better to avoid such complications here.)

$$P_{it} \propto \partial V / \partial S_{it}, \quad \text{for all } i \text{ and all } t \quad [2]$$

At time t , the value of species i would be $P_{it}S_{it}$. It follows that the value of the ecosystem itself would be $\sum_i P_{it}S_{it}$. Notice that this is a linear function of stocks, the weights being accounting prices.

In the section Institutional Failures and Poverty: Global versus Local Environmental Problems it is noted that a "project" can be thought of as a perturbation of the forecast X_{it} . So a project can be denoted as $(\otimes X_{1t}, \otimes X_{1t}, \otimes X_{2t}, \dots, \otimes X_{Nt})$, for $t \geq 0$. ($\otimes$ denotes an operator signifying "small difference".) (Note that for all i and all t , $\Delta X_{it} = \sum_j [\partial X_{it} / \partial S_{jt}] [dS_{jt} / dt] \Delta t$.) Some of the $\otimes X_{it}$ s would be zero. Nevertheless, the project would be expected to perturb future stocks of all the resources, since this is what a strongly coupled ecosystem would be expected to display.

Let r be the social rate of discount and let C_{it} be the unit cost of harvesting i at t . (C_{it} could depend on stock sizes at t . For example, the unit cost of fishing depends not only on the technology available for fishing and the price of fishing equipment, but also on the stock in the fishery: the larger the stock, the smaller the unit cost.) It follows that the present discounted value of the flow of net social benefits from the project is:

$$\int_0^\infty e^{-rt} [\otimes_i (P_{it} - C_{it}) \otimes X_{it}] dt \quad [3]$$

If expression [3] is positive, the project should be accepted; if it is negative, the project should be rejected.

It can be argued that projects, as it has been defined here, are merely "small" perturbations, whereas redirecting economic activity so as to avoid damaging an ecosystem irrevocably could involve drastic change. But it should be noted that one way to conceptualize a "large" perturbation is to regard it as the sum of a large number of small perturbations. A large perturbation (i.e., a large project) could then be evaluated by repeated use of expression [3].

However, if this route is not adopted, social cost-benefit analysis of large projects requires the project evaluator to estimate the large changes in V consequent upon the adoption of large changes in economic policy. Accounting prices, reflecting as they do the social worth of marginal units of the various resources (expression [2]), would then not suffice: the evaluator would need to integrate over the marginal units so as to estimate "consumer surpluses," to use a term familiar in economics.

So far, so good. But there is a problem with the account: it is unreasonable to assume that V is differentiable, even continuous, everywhere. Ecosystems are nonlinear systems (eqn [1]). So even if it were reasonable to suppose that V is differentiable everywhere else, it would be wrong to suppose that it is even continuous at loci of points separating different basins of attraction (i.e., at separatrices). (An important early contribution, showed via an example that if harvest functions are optimal, V is continuous even at points where harvests are discontinuous. This means that accounting prices are not uniquely specified at such points (Skiba, 1978). However, V can be shown to possess right- and left-partial derivatives there. So, accounting prices can be used for evaluation purposes, even though they are not uniquely given at every point on the space of resource stocks.)

But if the X_{it} s are not optimal, V can be discontinuous at points on a separatrix. This causes problems, because accounting prices cannot even be defined at such points. Let the

Figure 2 Nonlinear model depicting value of species in relation to function of the stock, where the ecosystem comprises a single species.

implications of this for biodiversity valuation and social cost-benefit analysis be studied.

Experience with nonlinear models of ecosystems tells that, under the assumptions made here, there could be at most a countable number of separatrices. This is fortunate, because it means that points on the stock space that are “troublesome” are nongeneric. So assume this. In Figure 2 the matter is illustrated in the context of an ecosystem comprising a single species. The figure depicts the case where the separatrix is a single point, S^* , reflecting a threshold. For example, it could be that, under the harvesting policy $X(S)$, the species would become extinct if its population were below S^* , but would be harvested in a sustainable manner if the population more than S^* . So stocks to the right and left of S^* represent different basins of attraction. Reasonably enough, Figure 2 depicts a case where the value of the species, $V(S)$, is an increasing function of the stock. It is assumed to be continuous (indeed, differentiable) everywhere except at S^* , where it jumps (an irrevocably dying population being a lot less valuable than a sustainable one). Of course, the location of S^* depends on $X(S)$: change the harvesting policy slightly, and S^* will shift slightly. The influence of $X(S)$ on S^* is something that has to be estimated if ecologists and economists are to offer policy advice.

Now, except by fluke the stock at $t=0$ would be different from S^* . So then assume it is different. If the project is sufficiently small, the account of social cost-benefit analysis discussed earlier remains valid: the system would not cross into a different basin of attraction. But a good theory should be extendable to fluke cases. Moreover, actual projects are frequently not “small,” so acceptance of a project or its rejection could mean that the ecosystem is eventually in one basin of attraction rather than in another. How can this theory be extended the theory to handle the possibility that the ecosystem crosses into a different basin of attraction? In particular, is the repeated use of expression [3] a feasible means of evaluating projects?

It is as well to be clear where the problem lies if one were to try using expression [3]. The problem lies in that an accounting price cannot be defined at S^* . This means that a project that involves the stock passing through S^* cannot be evaluated by means of a linear index of social profitability. The height of the jump would have to be estimated and put to use in social cost-benefit analysis. Ecologists and economists would have to combine their expertise to locate S^* and identify the functional form of $V(S)$, both on the right and on the left of S^* . Estimate the height of the jump involves measuring “consumer surpluses”, a point noted earlier. In short, at least one small project in the series of small projects that add up to the large project in question would not be assessable by means of expression [3]. This makes for difficulties.

Having noted this, there is a way to avoid the problem. The authors have been studying deterministic systems. Introducing uncertainty about the location of S^* can help matters by smoothing the value function. To see how, imagine that $V(S)$ represents the expected value of the resource’s social worth at S . If the location of S^* were a smooth probability distribution, $V(S)$ would be a continuous, even a differentiable function. In this case an accounting price of the resource would be definable at all S (S^* being a smooth random variable). A linear index of the social profitability of projects could then be constructed. The methods of social cost-benefit analysis outlined earlier would remain valid.

It is not often that introducing realism simplifies analysis. Valuing biodiversity would seem to be an exception.

Conclusions

The US National Academy of Science described the fundamental challenge in valuing ecosystem services as “providing an explicit description and adequate assessment of the links between the structure and functions of natural systems, the benefits (i.e., goods and services) derived by humanity, and their subsequent values” (Heal *et al.*, 2005, p. 2). Despite the strides already taken in meeting this challenge, however, there are few economic studies of the value avoiding thresholds. Nor are there many studies of the value of the capacity of systems to keep functioning when subject to shocks or stresses. This is partly because there is still disagreement among ecologists of the role of biodiversity in maintaining either the stability or the resilience of ecosystems. At small scales an increase in species richness and the diversity of overlapping functional groups of species enhances the level of functional diversity, and hence both ecological stability (Tilman *et al.*, 2005) and resilience. At larger scales, the evidence is less clear. However, it is likely that maintaining a portfolio of options in ecosystems does strengthen their capacity to respond to shocks and stresses in constructive and creative ways. There is certainly evidence for this is coupled social-ecological system. In agricultural systems, for example, greater crop diversity has been shown to reduce the variance of both agricultural yields and farm incomes (Di Falco, 2007). Whereas the homogenization of agroecosystems has sometimes increased yields in the short run, it has often been at the cost of increasing variance in yields due to the increased vulnerability to pests and pathogens it brings. This in turn increases reliance on

pesticides that are potentially damaging to both humans and other species. In this case, the value of biodiversity – at least the value of the portfolio of cultivated species in the system – is the value to society of keeping crop production risks within acceptable bounds.

The wider economic literature has tended to identify biodiversity with conservation, and sometimes even more narrowly with the preservation of endangered species. It has also tended to identify biodiversity change with biodiversity loss. But the extirpation or extinction of endangered species, important though it is, is only one dimension of biodiversity change. Biodiversity change affects the functioning of ecosystems in ways that potentially affect a large array of interdependent ecosystem services. Actions designed to enhance one service frequently compromise other services. In very many cases the effect of biodiversity change is to alter the capacity of the system to function over a range of environmental conditions. So the effect may not be immediate. In fact it may not be felt for many years. The valuation of biodiversity requires that one understands how a change in the mix of species within some functional group affects human wellbeing at various spatial and temporal scales. It also requires that one understands which effects of biodiversity change are captured in market prices and which are not.

It is not always the case that biodiversity loss is bad. Many very important ecosystem services depend on the simplification of ecosystems, and that frequently means the extirpation of particular populations. Protecting people against the effects of disease means controlling pathogens, even to the point of driving them to the extinction in the case of smallpox and rinderpest. The economic problem of biodiversity change is not that ecosystems have been simplified; it is that many of the less direct consequences of simplification are not taken into account by those responsible. The indirect effects of simplification on other ecosystem services, on other people, or on other places are frequently ignored. Such externalities of biodiversity change frequently impose costs on those who either have no voice (future generations) or are least able to cope with the effects (the poorest among the present generation). That is the economic problem of biodiversity change.

Glossary

Conservation tourism Tourism which yields a net positive benefit for conservation of biodiversity, i.e. where contributions to conservation outweigh environmental impacts.

Ecotourism Commercial tourism which is based on relatively undisturbed natural environments, and which takes steps to minimize environmental impacts, provide environmental education to clients, and contribute to environmental conservation.

Nature-based tourism Tourism where nature provides the primary setting or attraction.

Tourism Travel for leisure, recreation, or vacation; for economic statistics, generally only overnight travel is included.

Visitor Term used by protected area (parks) management agencies to include everyone entering the park, either as an individual or a client of a commercial tour operator.

Introduction

Biodiversity is a tourist attraction. Tourism creates impacts on biodiversity, but can also help conserve it. There is a mass-market wildlife tourism industry which relies on large charismatic icon species, but also a smaller, more sophisticated and specialized sector focusing on rare birds, mammals, reptiles, and plants. Tourism and recreation are the main uses permitted in most of the world's protected areas. Many people visit parks only for recreation; they create impacts and impose management costs, but may also provide a political constituency for protected area agencies. In developing nations, tourism can also be a significant source of conservation funding, in private as well as public reserves. There are also private reserves in developed nations, but these rely more on philanthropy than tourism.

Across both developed and developing nations, the degree of interaction between the tourism industry and the conservation sector is small relative to the overall scale of either. Protected areas are established and funded by governments principally for conservation; the major threats to biodiversity are from large-scale primary and extractive industries, both legal and illegal, and from continued expansion of human populations and residential settlement; and most tourism is urban. Worldwide, it has been estimated that about one-fifth of the global tourism industry operates in outdoor natural environments; and only a tiny fraction of 1% contributes directly to biodiversity conservation. Some of these contributions, however, seem to be critical for particular species and ecosystems (Buckley, 2009, 2010a).

Geography

Tourism has a well-defined though continually changing global geography. Most tourists originate in rich Northern cities; and they travel both to other such cities, and to rural, protected and wilderness areas in both the developed and

developing world. The patterns in the numbers of tourists, the activities they do, and the money they spend is determined by a combination of human and physical geographies. In particular, the use of tourism as a conservation tool is highly vulnerable to wars, crime, terrorism, and political instability in destination areas; and also to marginal changes in the economic conditions, currency exchange rates, and relative airfares on different routes.

Both biodiversity and conservation also have their own geographies, so that species are under much greater threats in some parts of the world than in others. Either as a tool or a threat in conserving biodiversity, tourism is most significant in areas where other threats are most severe and least effective. To improve resilience of protected areas to climate change, for example, other sources of impact need to be reduced, and these include impacts from tourism and recreation. Political and financial support from tourism, however, may be more critical where conservation reserves or endangered species are poorly protected because of factors such as poaching, invasive species, encroachment, or extractive industries, than in areas where parks agencies are operating effectively.

The significance of any contribution from tourism to conservation depends on the economic scale of the tourism sector in the area concerned, and on the effectiveness of local laws and institutions to minimize the impacts of tourism and harness it for conservation. The first aspect is straightforward. Some, at least, of the world's most biodiverse regions do indeed receive large numbers of international tourists. The second aspect is highly problematic. There is an extensive literature on: whether or not public protected areas should charge fees; how these should be structured; whether or not they outweigh visitor management and fee collection costs; who should use any net funds raised; and for what purposes. There is also an extensive literature on private organizations which run tourism operations specifically to support conservation.

There does not seem to be any nation which has successfully harnessed tourism to support conservation at a large

scale. Indeed, it is by no means clear that this is a valid public policy goal, except in countries with strong overall economic dependence on nature-based tourism. For countries with other large industry sectors, or a large urban and resort tourism industry, it may well be more logical to fund conservation from resource royalties and corporate taxation across all sectors. Logging and mining, farming, and fisheries are continually reducing the conservation value of public lands outside the protected estate. Tourism is indeed a major user of protected areas, but still has lower impacts on conservation than those of the extractive industries.

Attractions

A significant subsector of the tourism industry worldwide relies on particular plant and animal species as the primary attractions for commercial tourism products. There is a broad distinction between products and packages based on the opportunities to see a single charismatic icon species, and those which provide opportunities to see a diverse assemblage of different species (Buckley, 2010b). Examples of the former include: the Big Five of sub-Saharan Africa; the big cats such as tiger and jaguar; bears and pandas; whales and dolphins; and the larger primates such as gorilla, orangutan, and chimpanzees. There are substantial wildlife tourism subsectors which rely on each of these. There are also individual icon species which are perceived by tourists as small and cute rather than large and dangerous. Examples include meerkat, lemurs, bushbabies, and sugar gliders. Lemurs as a group, for example, are a major attraction for tourists to visit Madagascar.

There is a substantial international birdwatching tourism subsector which focuses on the diversity of bird species encountered, in the shape of lifetime lists. There are particular icon species which birdwatchers want to see in individual destination areas, but they choose destinations which will give them a chance to see many species in the same area. This also applies for tourism products based on flowering plants, known as wildflower tours, where people want to see a diversity of spectacular species flowering simultaneously. There are specialized subsidiaries, such as those which focus on orchids or proteas. There are also tourism products which focus on single individual trees, typically those which are very large and old or those which have some historical cultural significance.

There are some wildlife species which are perceived as iconic to particular landscapes, and used in tourism marketing even if few tourists actually see them. Examples include: wolves in wilderness areas of North America and parts of Europe; the Mikado pheasant in the mountains of Taiwan; and narwhal in boat-based tourism in the Arctic. While mammals and birds are by far the most important wildlife for tourism, there are also a number of reptiles and amphibians which are valued by tourists. Examples include the Komodo dragon in Indonesia, frilled lizard in Australia, nesting turtles on tropical beaches worldwide, chameleons in Madagascar, and nocturnal frog hunts at various rainforest lodges. There are small-scale tourism operations based around particular plant species such as the rafflesia flower of tropical southeast Asia, the welwitschia plant of the Namib Desert, and the spiny octopus

tree of Madagascar. There are also a number of landscapes famed for tourism which owe their form and attractiveness to particular types of vegetation. Examples include the redwoods of California, the saguaro and ocotillo of the American southwest, the heather moors of Scotland, the peat bogs of Ireland, the savannahs of Africa, the grasslands of central Asia, the eucalypt forests of Australia, and many more.

Impacts

At a global scale, tourism currently contributes around 5% of total anthropogenic carbon dioxide emissions and around 14% of global greenhouse gas impacts when other gases are also considered (Scott *et al.*, 2010). About four-fifths of this is from air travel. Climate change is already affecting the range and survival of species and ecosystems worldwide, and tourism is thus contributing to these impacts. Airlines and car rental companies offer carbon offsets, but few passengers purchase them. The effectiveness of current offset programs is highly questionable, since they are based on marginal adjustments between land uses and energy generation technologies which have high environmental impacts and a history of public subsidies. At current offset prices, the additional cost is far below the levels which would reduce air travel through economic effects (Tol, 2007; Buckley, 2011).

The majority of tourist accommodation is urban, and hotels and holiday apartments are subject to the same environmental regulations and planning procedures as other urban buildings of comparable size. They create impacts on biodiversity through *pro rata* contributions, firstly, to the impacts of providing construction materials, operational consumables, and water and energy; and secondly, to the generation and disposal of solid and liquid wastes and atmospheric emissions. The tourism industry in many countries also relies heavily on large stand-alone resorts, especially in coastal and mountain areas. Ski resorts and associated residential developments can have considerable impacts on mountain ecosystems, including clearance, terrain modification, fresh water extraction, noise, light, and roadkill. These impacts are exacerbated as the resort operators respond to climate change by extending retail precincts and residential property developments, and expanding both summer activities and winter snowmaking (Pickering and Buckley, 2010). In Australia, for example, ski resorts are one of the principal factors threatening the endangered mountain pygmy possum.

In pristine or relatively undisturbed natural environments of high value for biodiversity conservation, activities associated with tourism and recreation can generate a variety of direct and local impacts. The degree of impact depends strongly on the type of activity and on when, where, and how it is carried out (Buckley, 2004). There are many instances where helicopters and light aircraft flown at low altitude, for example, have created significant local impacts on caribou, polar bear, dall sheep, nesting pelicans, and other species. An off-road vehicle (ORV) driven slowly and carefully can often approach wildlife within meters or even closer, without causing disturbance; whereas ORVs driven fast and heedlessly can cause significant damage and disturbance to soil, vegetation, and wildlife. Such impacts are particularly severe for

competitive events, whether formal or informal, such as desert races, dune driving, and mudboggling. There are a number of reported instances where off-road vehicles have caused major losses in local populations of small mammals, ground-nesting birds, reptiles and amphibians, and beach-dwelling crabs. Both wheeled vehicles and livestock can also act as vectors of weeds and pathogens. Hikers also disperse weed seeds and fungal propagules on footwear and clothing (Pickering and Mount, 2010; Whinam *et al.*, 2005). Hikers and other non-motorized outdoor recreationists, especially with dogs, can also cause disturbance to birds and mammals, which may affect foraging energetics if repeated frequently.

Conservation

The potential for tourism to contribute to conservation is promoted extensively by tourism industry associations, but this is largely a political lobbying tool. There are indeed a small number of commercial tourism enterprises which do appear to make a positive net contribution to conservation and biodiversity, but these are exceptions: The majority of the mainstream tourism sector makes a large net negative impact on biodiversity through the mechanisms outlined in the preceding section. Tourism industry lobbyists routinely suggest, for example, that merely giving people the opportunity to visit areas of high conservation value will somehow convert those people to active conservation lobbyists, but there is no evidence that this actually happens. Tourism is often touted as one justification for the declaration of new protected areas, but these lobbying efforts are largely by conservation groups rather than the tourism industry itself.

Where public parks agencies charge visitor entrance or activity fees, commercial tour clients generally have to pay these in the same way as independent recreational visitors, though sometimes at slightly different rates. Commercial tour operators in public parks may also have to pay a basic license or permit fee, though this is usually at a nominal level (Buckley, 2003a). In developed nations, funds raised through visitor fees typically do not cover the costs of parks visitor infrastructure and management, so commercial tour operators are effectively subsidized by general tax revenue. In developing nations, especially where international visitors pay significantly higher fees than local residents, these revenues may indeed make a significant contribution to park's agency budgets. The broader economic activity associated with inbound park-based international tourism may also provide significant political support for conservation at a national level.

The case of Madagascar is often cited; though this case also exemplifies the extreme vulnerability of conservation tourism to political instability. At least Madagascar's lemurs are well known, so that international concern was quickly created following the 2009 coup. Other countries, for example, in West Africa, may suffer similar depredations of endangered species through poaching, logging, and hunting, without anyone knowing. It is not clear, however, whether international public knowledge of Madagascar is linked to wildlife tourism, or solely to wildlife documentaries and the cartoon movie *Madagascar*. While there are indeed some individual tour operators who advertise the conservation significance of

their wildlife tours to Madagascar and similar areas, the main conservation mechanism seems to be from local economic contributions during the tours, rather than any larger-scale political action by the clients.

In a number of developing nations, private reserves and community lands are similar in scale, or indeed larger in total area, than the public protected area estate. Such reserves are not necessarily managed in the same way as national parks, but they do at least show a broad-scale change in land use, for example, from cattle grazing to conservation. The principal financial incentive for land owners to establish private reserves, in countries such as the USA, Brazil, and South Africa where they are common, is through land tax and income tax systems. Only a small proportion relies on tourism as a significant income stream; and in many cases this is based on hunting safaris rather than wildlife watching. Either approach can potentially yield benefits for biodiversity more broadly, but this depends on the details of land management practices.

A proportion of these private and community reserves, especially in sub-Saharan Africa and South America, are indeed managed for conservation and are funded specifically by commercial wildlife tourism (Buckley, 2010a, b). The best known examples operate at the upper end of the market, with luxury lodges offering good opportunities to watch icon wildlife species at close range. Less luxurious models are also widespread and numerous, but somewhat less visible.

There have been a number of attempts to catalogue enterprises marketing themselves as ecotourism (Buckley, 2003b; Zeppel, 2006), but only a small proportion of these make a net positive contribution to the conservation of biodiversity (Buckley, 2008, 2010a). In one or two cases, it has been possible to quantify the contribution as a definable percentage of the remaining global population of particular endangered species which owe their existence specifically to conservation tourism. There is as yet, however, no aggregate estimate of the total contribution to conservation of biodiversity which may be made by the commercial tourism sector, even without allowing for conservation costs through the large-scale impacts of mainstream tourism.

Conclusions

Links between tourism and biodiversity may be summarized as follows: (1) About one-fifth of the global tourism industry relies directly on biodiversity. (2) Most of the mainstream tourism industry generates diffused but large negative impacts on biodiversity, plus smaller localized direct impacts from some resorts and activities. (3) Outdoor and nature tourism generates broad political, and to some degree financial, support for protected areas, especially in developing nations, but this is uncertain and unquantified. (4) A small number of specialized conservation tourism enterprises do make demonstrable net positive contributions to conservation of particular endangered species, principally through the establishment, management, and funding of private and community reserves. (5) This model, however, depends heavily on political stability, currency exchange rates, and low airfares, and is itself a contributor to global climate change. (6) There is

continued contention, even at the most expert level, as to whether conservation is better served by coupling it or decoupling it from commercial tourism, and by what precise mechanism. (7) Many different approaches have been tried or suggested, with various degrees of success depending on the detailed circumstances. While the number of case studies is continuing to increase, general patterns remain elusive. (8) Tourism has definite negative and potential positive effects on biodiversity, and has not yet been harnessed routinely so as to live up to its potential as a conservation tool. Of course, the commercial tourism industry does not see itself as a conservation tool, but as a set of profit-making enterprises, so this situation is likely to continue.

Glossary

Compensated demand curve Demand curves represent how changes in price impact the quantity demanded of a given good. The compensated demand curve is a demand curve that ignores the income effect of a price change, only taking into account the substitution effect. To do this, utility is held constant and is unaffected by the change in the price of the good.

Compensating variation Compensating variation is the amount of money a consumer would need to be paid, or the amount of money that the consumer would need to pay, to be just as well off after a change in the price of a product which the consumer might buy.

Consumer surplus Consumer surplus is commonly defined as the area beneath the uncompensated demand curve and above the market-clearing price that consumers must pay for the good.

Contingent valuation A method of eliciting stated estimates of willingness to pay or willingness to accept for a given non-market good through hypothetical situations in which the provision of the good changes.

Ecosystem services Benefits that accrue to society as a result of functioning ecosystems.

Environmental production function Analog to the more traditional production functions from economics, in which inputs are combined using a given technology to create an output for consumption. Environmental production

functions are used to describe how functioning ecosystems produce goods and services enjoyed by society.

Equivalent variation Equivalent variation is the amount of money that must be given to (or taken from) an individual in lieu of a change in the price of a consumed good to make them just as well off as they would have been with the price change.

Hedonic pricing model A means of attributing portions of the price of a good with many characteristics (e.g., a house or a car) to each of those characteristics.

Revealed preference A method of exploiting the relationship that exists between individual behavior and environmental attributes to assign value to non-market goods.

Stated preference A method of eliciting the value of a non-market good through an individual's stated behavior in a hypothetical setting.

Travel cost method The travel cost method estimates the value of non-market environmental goods, using the cost of arriving at locations with different environmental amenities to estimate the value of changes in the quality of the sites.

Uncompensated demand curve Demand curves represent how changes in price impact the quantity demanded of a given good. The uncompensated demand curve illustrates the consumer's consumption bundle at each wealth and price combination, assuming that she is a utility-maximizer.

Introduction

When choosing which patches of old-growth Douglas firs to harvest in the mountains of Oregon, a timber company might take note of the tree density or the slope, as these factors directly impact the profit of the company's operations. It is less likely that the company would voluntarily avoid harvesting trees from a steep hillside because the resulting increased release of sediment from the denuded hillside could increase costs for the reservoir operator downstream. Less likely still is the possibility that the timber company would factor in the impacts of extracting old-growth trees on the population viability of different forest-dwelling species.

In practice, the logging industry in the Pacific Northwest did not voluntarily adjust its operations in response to the negative environmental impacts associated with the clear-cut harvest of old-growth trees from the Pacific temperate rain forest. The clear-cut harvest of timber in Oregon, which began in the late 1820s, continued as the dominant management approach until the National Forest Management Act passed in 1976. The act did not prohibit clear-cutting, though it did restrict application of this harvest technique. In 1989, the US Fish and Wildlife Service designated the northern spotted owl as a threatened species in Washington, Oregon, and northern California, restricting land-use activities, including logging, on its habitat under the Endangered Species Act (ESA) of 1973.

These pieces of legislation set the status quo operation of the timber industry at odds with efforts to ensure the viability and continued function of these forest ecosystems.

Many loggers in the region voiced their displeasure with enforcement of the ESA, as they felt that their way of life was being sacrificed for a cause that did not clearly benefit social well-being. Following the listing of the northern spotted owl as a species covered by the ESA, bumper stickers appeared in the Pacific Northwest in support of the loggers. Examples include "Kill a Spotted Owl – Save a Logger" and "I Like Spotted Owls – Fried" (Satchell, 1990). Though framed in the context of species protection, the ESA has been implemented as a means of conserving habitat, presumably out of the belief that habitat conservation provides value to society. That said, this value may not accrue to the individuals whose activities are regulated, and the salience of this value to beneficiaries may not be obvious when discussed in terms of species viability. These facts contribute to the tension between forces of conservation and forces of conversion. This tension is what may have motivated the reframing of the habitat conservation issue in terms of ecosystem services, which deal, by definition, with the value of nature to humans.

The potential benefits to society of conserving these temperate rain forests in Oregon include but are not limited to maintenance of water quality in coastal tributaries that are home to commercially important salmon species and are used for human recreation, retention of sediment that might impact downstream reservoirs regarding both hydropower production and flood-prevention functions, and the sequestration and storage of carbon whose release into the atmosphere is associated with expected damages. In addition to this sample of benefits from intact forests in the Pacific Northwest, these forests are also essential habitat to multiple species of animals and plants whose survival depends on their continued existence. None of this suite of benefits is as directly tangible as the consumption of timber from the harvest of Douglas firs or the income associated with this harvest; however, this lack of familiarity and tangibility does not imply a lack of social value.

The choice between the conservation and conversion of extant habitat that continues to play out in the Pacific Northwest and elsewhere around the globe illustrates the trade-off that exists between the private benefits of conversion and the social benefits of conservation. Ensuring that land- and resource-use decisions provide the greatest amount of benefit to society requires the identification and quantification of the trade-offs inherent in such decisions. To achieve this goal, we must be able to value the benefits of habitat conservation, which must generally be forgone to enjoy the benefits of intensive resource management.

Under certain conditions, self-interested actors operating within a market system can achieve an efficient use and allocation of resources. However, several characteristics of land and other natural resources typically prevent markets for these goods from achieving their efficient use. There are external costs associated with habitat conversion, and several benefits provided by extant habitat are public goods: it is difficult to exclude downstream users from receiving the benefits of improved water quality (i.e., this good is nonexcludable), and carbon sequestration and storage by forests reduces the probability of climate change for every individual on the planet (i.e., this good

is nonrival). These two features of land and resource use have contributed to inefficient habitat conversion across the globe.

It would seem that regulatory and public policy mechanisms could increase social welfare through the increased protection of habitat and the provision of associated ecosystem services relative to the outcomes of unregulated markets. There are trade-offs associated with habitat conservation just as there are with habitat conversion, and there will be both winners and losers from such decisions. Those asked to forgo private returns in order to ensure increased social benefits will tend to challenge the implementation of such regulation. Quantifying the welfare implications of public policies aimed at ensuring the continued provision of ecosystem services requires an understanding of how ecosystem function is affected by human activity, how these effects alter the provision of services from these ecosystems, and how this change in provision affects social welfare.

Overview of Ecosystem Services

The Millennium Ecosystem Assessment (MEA, 2005) introduces four different categories of ecosystem service. The different characteristics across service categories impact efforts to value the individual services within each category. The first category, provisioning services, includes the services that are most familiar to society, such as agricultural products, seafood, and timber, among others. Provisioning services are ecosystem services that are directly consumed by humans and are often examples of renewable resources, a class of resource that has been well-studied by resource economists for nearly 70 years. These services are generally traded in traditional markets, and their enjoyment by society requires concerted effort by some members of society (e.g., the time, capital, and labor of farmers to harvest each year's crop). Even with markets for these provisioning ecosystem services, there are still externalities associated with their harvest, and the management of these provisioning services can significantly impact the quantity of service provision as well as its value to society. The value of these services comes from their consumptive use.

Regulating services impact human well-being through their regulation of natural processes. Examples of regulating services include the sequestration and storage of carbon by vegetation that helps to regulate climate, the mitigation of surface flows associated with storm events by vegetation that helps to regulate flooding extent, and the retention of nutrients and other pollutants by vegetative cover on the landscape that helps to regulate the quality of downstream water bodies. Regulatory services are typically not associated with markets, so government intervention is essential to ensure that there is an adequate provision of these services on the landscape. These services are typically provided without direct costly activity by humans. The value of these services comes from their use, though these services are quasi-public goods in that they are simultaneously enjoyed by groups of beneficiaries (i.e., they are nonrival and nonexcludable to segments of the population).

Cultural services cover a broad array of services related to both the direct and indirect social benefits of functioning natural systems. This umbrella of services runs from the enjoyment of outdoor recreation to the spiritual calming and

restoration of either access to or knowledge of areas of scenic beauty and cultural importance. Esthetic benefits such as the enjoyment of scenic coastal views, as well as the educational value of functioning natural systems, are included in the cultural ecosystem services category as well. Recreational opportunities and esthetic benefits are unique among the cultural services in that occasionally markets can be used to value these services, whereas the cultural, educational, and spiritual services are typically not associated with markets. The value of these services exists due to interaction with nature, directly (e.g., the satisfaction from catching or eating salmon) or indirectly (e.g., the benefits of having water available to irrigate crops that are eventually grown to feed humans) or through use, as well as the knowledge of or satisfaction from the existence of nature, which environmental economists refer to as “nonuse” value. Furthermore, there are both consumptive use values, as in the case of eating freshly caught fish, and non-consumptive use values, as in the case of time spent canoeing the tributaries of Chesapeake Bay.

The final category of ecosystem services defined by the Millennium Ecosystem Service (MA) is the supporting services. These services represent natural processes that are directly responsible for the composition of each ecosystem though perhaps only indirectly related to the ecosystem services provided by that system. Examples of these processes include primary production, nutrient cycling, and soil formation. There are no markets for these services, and they are not typically valued directly; instead, they are acknowledged as contributing to the other categories of services that provide more easily quantifiable value to society. In economic terms, these services can be thought of as inputs to the production of the other categories of ecosystem services that are directly valued by society.

Ecosystem services are the outputs that result from a combination of different inputs. Cell phones, and many other products that we consume, are produced using a combination of raw materials, labor, and capital through a specific technology. Similarly, ecosystem services are produced by a combination of ecosystem components, both biotic and abiotic, through the function of that ecosystem. An ecological production function specifies the output of ecosystem services that are provided by an ecosystem given its condition and processes. These functions will vary across space due to site- and ecosystem-specific relationships.

Once an ecological production function is specified, researchers can quantify the impact of landscape change on the level of ecosystem-service outputs. In the past two centuries, human alteration of ecosystems on a large scale, such as the conversion of extant habitat to single-crop agriculture, or monoculture, led to an increase in some provisioning services (e.g., food production) at the expense of many regulating, cultural, and supporting services (MEA, 2005; Vitousek *et al.*, 1997). In the example of timber harvest in the Pacific Northwest, the easily definable and tangible value of Douglas firs for their timber led to massive consumption of this ecosystem service and a simultaneous loss of most other services associated with temperate coastal forests.

The production function through which biophysical processes in an ecosystem are converted into ecosystem services is impacted by several ecosystem characteristics. The plant and animal species that live within an ecosystem are important

features of the system. Although the dominant vegetation type associated with an ecosystem has been shown to impact the quantity of ecosystem services produced by the system, the relationship between biodiversity and ecosystem services is less clear.

Ecosystem Services and Biodiversity

The traditional motivation for conservation has been the protection of wildlife, especially the charismatic species, that live in the areas of interest for conservation. Generally, this approach sets tangible benefits of intensive land management against the fate of different species chosen to represent the health of the ecosystem of interest. In many instances, as in the case of the northern spotted owl, the value of the representative species to society is not easily defined, making it difficult to compare to the forgone profits associated with habitat conservation.

Although there is a consensus among natural scientists that human action has altered the species composition of many ecosystems through species invasions and extinctions, there are still uncertainties regarding the impacts of varying species composition and diversity on ecosystem function (Hooper *et al.*, 2005). Experimental work conducted in the grassland prairies of Minnesota suggest that species diversity increases the productivity of a system as measured by biomass (Tilman *et al.*, 1997). However, it is not well understood if such results will extend to impacts of altered diversity for non-primary producer species.

The introduction of the term “ecosystem services” and the focus on the benefits to society of functioning ecosystems was partially motivated by the challenge of convincingly conveying the importance to humanity of ensuring the continued existence of various animal and plant species. Although the value of the northern spotted owl might not be clear to the average policy maker or landowner, that same policy maker or landowner might be familiar with the importance of clean water to society. By connecting the forests that are home to the owl to the idea of water filtration by the trees in the forest, the societal trade-offs between logging and forest conservation may become more salient to people affected by the choice between forest conservation and conversion.

Maintaining biodiversity is not typically considered an ecosystem service. Although there is some expectation that a focus on ecosystem services will ensure the continued existence of different species, the shift in focus to ecosystem services from species conservation clearly aims to highlight the value of functioning ecosystems to humanity. Understanding the different approaches that can be applied to value nature is useful in determining which approach might be most appropriate for a given policy context or land-use decision.

Definition of Value

In discussing the value of nature, there are two alternative philosophical approaches that can be used to frame the issue. The anthropocentric approach claims that natural things and functioning ecosystems are of value only to the extent that

they provide satisfaction to humans. The biocentric approach asserts that the satisfaction of humans as well as that of other species should be considered in determining the value of extant habitat and nature. [Goulder and Kennedy \(2011\)](#) provide a more-comprehensive discussion of the concepts that are briefly introduced here.

Although the anthropocentric approach assigns value based solely on benefits that accrue to humans, this does not imply that it offers a defense for the total exploitation of nature. This approach asserts that we should assign value and therefore protect nature and other species only because humans gain satisfaction or well-being from doing so. As such, if people feel that the protection of nature or other nonhuman species is truly beneficial to human satisfaction or well-being, then the anthropocentric approach will place significant value on nature and these other life forms.

The total value that is calculated under the anthropocentric approach represents the sum of values from a suite of different benefits that accrue to humans from nature. Broadly, the total value is the sum of both use and nonuse values. As previously mentioned, use values can be categorized as direct or indirect use values. Finally, nonuse values, which involve no direct or indirect interaction between humans and the benefits from nature, can provide significant satisfaction to members of society.

Unlike the anthropocentric approach, the biocentric approach gives weight directly to the well-being of all species. As a result, the biocentric approach allows for the possibility that other species and the habitats in which they exist can be of value even if the value does not directly or indirectly accrue to humans. This component of value, which is unrelated to humans, is often referred to as “intrinsic value.”

The impetus for calculating the value of ecosystem services is to help inform resource users and policy makers in evaluating potential resource uses and policy mechanisms. These decisions are frequently evaluated through benefit–cost analysis, which ranks alternatives based on their net returns to society, identifying the net gain to society of choosing one policy alternative over another.

The benefit–cost technique involves summing all of the gains associated with a given policy option and then subtracting all of the losses of that same option to establish the net gain of each option before identifying the policy option with the greatest net benefit. Part of the controversy surrounding the ESA in the USA is that the act specifically forbids the use of economic considerations to determine which species are eligible for protection. As a result, all species – from the red wolf and the North American cougar to the American burying beetle – are equally eligible to have their habitat protected by the act. This biocentric approach to land-use regulation, which unanimously passed the Senate in 1973, has become quite contentious as the value of conservation is measured in terms of the benefits afforded to the listed species, whereas the benefits of habitat conversion are measured using the anthropocentric approach and are therefore more easily relatable to landowners. By preventing application of benefit–cost analysis, the ESA has often been criticized as placing an overly onerous burden on private landowners ([Brown and Shogren, 1998](#)). Part of the reason for this criticism may be due to the fact that the connection between the

survival of the less-charismatic species protected under the ESA and the benefits of their survival to humans is tenuously understood at best.

The concept of ecosystem services is quite useful in highlighting the anthropocentric value of nature. By valuing each of the services provided, it is possible to quantify the anthropocentric value of a piece of habitat. The remaining sections of this chapter will focus on the anthropocentric approach to the valuation of ecosystem services. Having defined the approach to valuation that we will discuss in this chapter, we next consider the importance of assigning value to nature.

Assigning Value to Nature

When an objective is attained in the least-cost means, efficiency is a key concept and sought-after outcome in the discipline of economics. Under certain conditions, independent actors in competitive markets can achieve efficient social outcomes in the absence of government intervention. However, when these conditions do not hold, as is generally the case with regard to natural resources, government action is necessary to achieve efficiency. Generally, when the cost effectiveness or efficiency of a policy choice is being evaluated, the benefit–cost methodology is used to calculate what resources had to be used to achieve the given choice and what the benefit, or value, of that choice is to society. [Figure 1](#) illustrates the inefficiency that arises in the absence of government regulation when the production of a good, here converted habitat, has higher social costs than private costs. This negative production externality is a classic example of conditions under which government regulation can increase the efficiency of market outcomes. It is possible to measure

Figure 1 The external costs of habitat conversion. In the absence of regulation, Q_{mkt} units of habitat will be converted because this amount of conversion maximizes net private benefits (total benefits minus private costs). Q_{mkt} is more than the socially optimal amount of conversion because the costs of habitat conversion that accrue to other members of society, including the loss of the benefits associated with the various ecosystem services provided by the habitat, are not included in the maximization of private net benefits. By valuing these ecosystem services, we are able to identify the optimal amount of habitat conversion (total benefits minus total costs) and design policies to achieve this level of conversion.

the benefits and costs of a choice in different units. However, identifying the net benefits of an action is more straightforward if the benefits and costs of the action are measured in the same units.

Since before the passage of the ESA in 1973, there has been discomfort associated with the idea of placing an economic value on nature. Some of this concern has been rooted in the belief that by discussing nature in dollar terms, the value of conserving key habitat or protecting certain species would actually prove to be less than the value to society of converting this habitat into intensive agriculture production or another intensively managed land-use system. One other potential cause for the unwillingness to use financial terms to measure the importance of nature is related to the distinction between anthropocentric and biocentric values. By thinking of the importance of nature in economic terms, we are implicitly ignoring its biocentric value, thereby placing the welfare of humans ahead of that of all other living organisms. At the same time, efforts to define habitat value in the context of species diversity and viability have failed to resonate with broad elements of society.

The key goal of valuing nature is to ensure that resource-use decisions are being made in ways that result in the greatest returns to society. The shift to a focus on ecosystem services reflects an effort to emphasize the anthropocentric value of nature.

Ecosystem services are unlike most other market goods in that multiple services can be simultaneously produced by the same piece of habitat (e.g., a forest parcel provides carbon sequestration and storage, nutrient and sediment retention, and storm-peak mitigation). Because we are using the value of different ecosystem services to quantify the value of conserving extant habitat, we must take care to accurately value all services provided by a given patch of habitat. When policy makers and resource users choose to focus on the value of a single service, unintended consequences that induce additional costs on society can occur (e.g., Jackson *et al.*, 2005).

It is possible to estimate the value of ecosystem services in ways that more faithfully represent true social preferences than the approach of simply summing biophysical units, which implicitly assumes that each service is of equal per-unit value to society, a condition that may not hold in reality. The outcomes of these techniques are also consistent with the benefit-cost approaches that are used to determine the land- and resource-use decisions that provide the greatest benefits to society.

Quantifying the Value of Ecosystem Services

This section presents some of the economic theories and methods used to measure the welfare changes associated with changes in the provision of various ecosystem services. This effort has been undertaken in several different contexts previously (Goulder and Kennedy, 1997, 2011; Salzman, 1997; Heal, 2000; de Groot *et al.*, 2002; Boyd and Banzhaf, 2007). Bockstael and Freeman (2005) provide a very thoughtful and comprehensive discussion of assigning value to nonmarket goods in the broader context of environmental externalities, and the forthcoming discussion closely follows Sections 3 and

4 of their chapter in Volume 2 of *The Handbook of Environmental Economics*.

We present a general framework to measure the welfare implications associated with changes in the provision of various ecosystem services. The discussion here focuses on the direct welfare impacts of changes in ecosystem-service provision or prices. Understanding the full welfare impact of these changes requires an understanding of their impact on production of firms in different industries, which can be estimated using dynamic general equilibrium models.

The ecosystem services provided by a chunk of habitat are a function of the geologic, biophysical, and spatial characteristics of that piece of habitat. The function describing the production of ecosystem services from a piece of habitat will differ for each service of interest. Let $ES_{jx} = f_j(A_x)$ represent the quantity of ecosystem service j (e.g., nutrient retention by vegetation or storm-peak mitigation) produced by a piece of habitat x , with attributes given by A_x . We introduce the index x in recognition of the fact that the production of a given ecosystem service on a piece of landscape or seascape will vary spatially. There is a significant challenge in the practice of linking biophysical outputs with the inputs required by valuation efforts (e.g., hydrological models might estimate the tons of phosphorous retained by forests, but additional effort is required to relate that metric to the metric of lake clarity, which impacts lake swimming and the value of nutrient retention in the context of recreation).

Let H_x represent the measure of human activity that impacts the provision of ecosystem services on the x th unit of habitat. H_x might include increased water quality due to more-stringent regulation of effluent, human disruption of salmon nurseries, or changes in the area of forests due to increased zoning for residential development. So, we now have $ES_{jx} = f_j(A_x, H)$ as the expression that describes how a piece of habitat's characteristics and human activity on that piece of habitat combine to impact the production of the different ecosystem services provided by habitat on a given piece of landscape or seascape. The total production of ecosystem service j in the study area of interest is given by ES_j , where $ES_j = \sum_x ES_{jx}$. Certain ecosystem services, such as the production of agriculture, fish, or timber for harvest or storm-peak mitigation by forests, will directly impact human welfare, whereas others, such as the availability of water for crop irrigation or the presence of insect pollinators near agricultural land, will matter to humans because they enter as inputs to a production process, which we will describe as $Z(ES_j)$.

In the case of logging operations in the US Pacific Northwest, H might describe the conversion of coniferous forest to bare soil due to clear-cut logging of old-growth Douglas firs. This activity will have different impacts on the various ecosystem services provided by the previously forested land. With regard to the service of timber production, the harvest of the firs represents a realization of this service and a direct increase in welfare. Regarding the service of storm-peak mitigation, converting the forest to bare soil represents a reduction in the provision of this service, which will accordingly correspond to a direct decrease in welfare. Removing the firs from a portion of the landscape may increase the water yield and therefore the water available for downstream irrigation, which will indirectly increase welfare.

Space is especially important in the valuation of ecosystem services. First, the location of service-providing habitat in the landscape, not just the habitat type, can impact provision. Generally, services are provided by ecosystems at a location that is some distance away from the segment of the human population that benefits from this service (e.g., forests in upstream portions of watersheds help to reduce the volume and timing of surface flows associated with storm events that reaches downstream populated areas). Next, different services provide value at different spatial scales (e.g., carbon sequestration provides benefits to people around the globe, whereas filtration of surface water used for drinking downstream is only valuable to the population within the same watershed) making it challenging to estimate the full value of a given piece of functioning ecosystem with a single analysis at a given scale. Hein *et al.* (2006) provide further commentary on this challenge.

The links that exist between ecosystem function, the provision of ecosystem services that are of use to humans, the effects of human activity on the provision of these services, and the welfare impacts of service provision can be represented with a simple model, which does not imply that identifying any one of these links is a simple matter. Let W represent the level of economic welfare. Then the model that describes the direct and indirect utility provided by a given ecosystem service, indexed by ES_j , can be expressed as:

$$ES_j = \sum_x ES_{jx} = \sum_x f_j(A_x, H_x) \quad [1]$$

$$Z(ES_j) \quad [2]$$

$$W = W(ES_j, Z(ES_j)) \quad [3]$$

We are able to track the welfare impacts of proposed regulation or changes in land use by predicting how these regulatory and behavioral changes will impact the production of the focal ecosystem service and then using eqns [1]–[3] to calculate the resulting welfare change in monetary terms. The response of firms and individuals to regulation is by no means a certain outcome, and the prediction of these responses is a difficult goal that lies outside of the scope of this chapter.

Before proceeding with the exposition of estimating the value of a single service, we briefly return to the fact that habitat provides multiple ecosystem services simultaneously. The value of a given patch of habitat is given by the sum of the value of the suite of services provided by that patch, or $V_x = \sum_j W(ES_j, Z(ES_j))$. To accurately estimate the value of nature, we must accurately estimate the value of each of the provided services.

The model presented in eqns [1]–[3] represents a simplified view of the problem that de-emphasizes several challenges. Although we already briefly mentioned the issue of space, tracking the differential impacts of location on the provision of ecosystem services as well as appropriately incorporating the differential impacts of human activity on important characteristics of parcels across the landscape is a nontrivial task. That said, key spatial characteristics should be incorporated in the model. The temporal dimension also provides motivation to approach estimation of welfare impacts from ecosystem service provision with care. The issue of

time also warrants careful consideration, particularly because certain ecosystem services represent stocks (e.g., the salmon available for harvest), whereas others represent flows (e.g., the sediment retained by a forest). Furthermore, if considering welfare effects of long-term changes in service provision, it is important to remember that the ecosystem production function may vary across time due to climate change, and the production function that takes ecosystem services as inputs may also vary through time as technology changes, so that calculations made ignoring such changes will provide inaccurate estimates of welfare impacts.

In the following simple model of individual utility, we ignore uncertainty, allowing us to pinpoint how changes in inputs to the utility function alter utility. Let us first consider the case in which an individual's utility is a function only of private goods purchased, where the individual attempts to maximize her utility by choosing quantities of these goods to consume given an exogenous set of product prices and a fixed amount of personal income, denoted by M . The constrained utility optimization faced by the consumer is given by

$$\max U = U(X) \text{ subject to } P'X \leq M \quad [4]$$

where X is a vector of n goods and services and P is a corresponding price vector. The solution to this problem results in a set of n Marshallian demand functions given by

$$x_i = x_i(P, M), \quad i = 1, \dots, n \quad [5]$$

where eqn [5] represents the consumption of a given good that allows the individual to achieve her highest level of utility given her income and the prices of all goods. Substituting eqn [5] into eqn [4] results in an indirect utility function, representing utility as a function of prices and income based on the consumption decisions made by the individual when facing these prices with income level M

$$U = V(P, M) \quad [6]$$

Ecosystem services can be introduced in three different ways to a consumer's utility function. First, for services such as production of salmon or air quality in Yosemite Valley, ES_j could enter the utility function in eqn [4] directly. Other services such as vegetative pollutant retention that maintains downstream water quality for consumption might enter the utility function as an input to the production of a household produced good – in this case, the health status of the individual as given by $Z(ES_j)$. Regardless of whether the given ecosystem service directly impacts utility or only has an effect on utility through the production of Z , ES_j would appear as an argument of the indirect utility function described in eqn [6].

The third mechanism through which ecosystem services might impact an individual's utility is by affecting the production process of one of the private goods that the individual consumes. In this case, the welfare effects of a change in service provision would manifest themselves through changes in the price of the privately produced goods or inputs to their production, which could alter one or more elements of P or could alter M or both. As an example, it might be the case that the harvest of fir trees for their timber could result in a reduction in the capacity of the landscape to prevent sediment

from being carried into reservoirs during rainfall events. This result means that the sedimentation of the reservoir could occur at a faster rate than the operator of the hydropower station might have planned. As such, there could be an increase in the cost of power production, a resulting increase in the price of electricity, or possibly a reduction in rents to the hydropower owner and the income of plant employees. Under different conditions, the change in income alone could be used to measure the welfare impact, whereas other conditions would call for the inclusion of opportunity costs in the calculation of the welfare effects (See Freeman, 2003 for more details of this issue).

We have isolated the mechanisms through which ecosystem services impact individual utility. The change in utility resulting from a change in ecosystem-service provision could theoretically then be used to quantify the value of these services to the individual. Unfortunately, utility change is neither measurable for individuals nor additive across individuals, so we cannot use utility itself as a measure of welfare change. Instead, we can use the amount of money that must be offered or taken from an individual in conjunction with a change in the provision of ecosystem services to ensure that she maintains a constant utility level as our measure of the welfare impact of changes in ecosystem-service provision.

If we are interested in a small or marginal change in ES_j , we can identify the resulting marginal welfare change by differentiating the indirect utility function with respect to ES_j and M to identify the change in M necessary to compensate for the change in ES_j :

$$-\frac{dM}{dES_j} = \frac{\partial V / \partial ES_j}{\partial V / \partial M} \quad [7]$$

The expression in eqn [7] will be positive if ecosystem-service provision increases and negative if provision decreases. If the changes in ecosystem-service provision and the resulting welfare impacts are relatively large or nonmarginal, then the concepts of compensating and equivalent variation are used to measure the welfare effects of these changes. Compensating variation represents the amount of money that must be taken away from (or given to) an individual to make her just as well off after the change in ecosystem-service provision as she was before the change. We can implicitly define compensating variation using the indirect utility function as

$$V(P^1, ES_j^1, M^1 - CV) = V(P^0, ES_j^0, M^0) \quad [8]$$

where superscript 0 represents initial levels and superscript 1 denotes subsequent levels of the parameters, respectively. Presented in this way, the compensating variation has the same sign as the welfare change. For example, if the only change is an increase in ecosystem-service provision, meaning that $ES_j^1 > ES_j^0$, while $M^1 = M^0$ and $P^1 = P^0$, then the individual will clearly have to give up some income to be indifferent between the initial and subsequent parameter values, so that $CV > 0$.

Although compensating variation uses the utility level of the initial condition as the base case, equivalent variation uses the utility level of the subsequent condition as the base case. The equivalent variation is defined as the amount of money that must be given to (or taken from) an individual in lieu of a change in the quantity of ecosystem-service provision

to make her just as well off as she would have been with the change in provision. We can implicitly define equivalent variation using the indirect utility function as

$$V(P^1, ES_j^1, M^1) = V(P^0, ES_j^0, M^0 + EV) \quad [9]$$

Once again, we see that equivalent variation, defined in this way, has the same sign as the welfare change.

Having identified the three pathways through which changes in the provision of ecosystem services might impact welfare and introduced two measures to quantify the welfare impacts of such changes, we can now explore how compensating and equivalent variation can be used to quantify these welfare impacts. Thus far we have implicitly expressed CV and EV in terms of the indirect utility function, which expresses an individual's utility as a function of prices and income based on her consumption decisions made in an attempt to maximize utility with her fixed amount of income. We can now explicitly define CV and EV in terms of an individual's expenditure function.

The expenditure function is obtained by identifying the consumption decisions that would be made by an individual who would like to achieve a threshold level of utility while minimizing the cost of her consumption choices. The expenditure function is derived by solving the following constrained optimization problem:

$$\min P'X \quad \text{s.t. } U(X, ES_j) \geq U^0 \quad [10]$$

where P represents the vector of product prices, X represents the vector of consumption units, and U^0 represents the threshold level of utility that the individual is attempting to achieve. It should be noted that the objective in expression [10] represents the dual to the utility maximization problem presented in expression [4].

By substituting the cost-minimizing demand for X into the objective function in eqn [10], we can identify the minimum amount of money necessary to achieve the targeted level of utility, given market prices and ecosystem-service provision,

$$e = e(P, ES_j, U^0) \quad [11]$$

We are now able to explicitly describe compensating and equivalent variation of a change in prices or ecosystem-service provision. The compensating and equivalent variations for a price change are given by

$$CV = e(P^0, ES_j^1, U^0) - e(P^1, ES_j^0, U^0) \quad [12]$$

and

$$EV = e(P^0, ES_j^0, U^1) - e(P^1, ES_j^0, U^1) \quad [13]$$

whereas those for a change in the provision of the focal ecosystem service are given by

$$CV = e(P^0, ES_j^1, U^0) - e(P^0, ES_j^0, U^0) \quad [14]$$

and

$$EV = e(P^0, ES_j^0, U^1) - e(P^0, ES_j^1, U^1) \quad [15]$$

where

$$U^i = V(P^i, ES_j^i, M) \quad i = 0, 1 \quad [16]$$

The majority of the benefits that accrue to humans as a result of functioning ecosystems are goods that are not traded on traditional markets. As a result, most of these services will impact welfare through changes in the quantity of provision as opposed to impacts on the production of market goods by firms that will have price effects. That said, agriculture, fisheries, and timber are important components of the global economy, and changes in the provision of these ecosystem services will impact welfare not only through changes in the quantity of the service itself but also through changes in the market prices for these goods.

Thus far, we have focused on estimating the impacts of changes in the price or quantity of a particular ecosystem on an individual's welfare. In the context of benefit-cost analysis, we would like to understand which resource-use options provide the greatest benefits to society. Doing so requires a method of aggregating the estimates of individual welfare impacts over the relevant portion of society. Moving from individual to social welfare outcomes could be accomplished by summing up the welfare measures across relevant individuals who might be differentially affected due to variation in preferences or because the welfare changes themselves vary. Still, if the change results in net welfare gains to some and net welfare losses to others, when should such a change be deemed beneficial to society? One approach involves summing the CVs across all affected individuals, with the policy change deemed beneficial if this sum is positive (Kaldor, 1939) (remember that CV represents the compensation necessary for those made worse off by the policy to accept it as well as the willingness to pay of those who benefit from the policy to ensure it occurs). This approach recommends such policy changes that make it possible for those who benefit from the change to compensate those who suffer from the change. In practice, those transfers do not occur, so this method does not truly address the potential equity issues of policy evaluation, particularly when it is possible for the benefits to accrue unevenly across income levels in society. The inability to clearly resolve distributional concerns regarding policy changes is a key reason that benefit-cost analysis can be insufficient to decide policy matters.

In addition to the equity issues associated with aggregating estimates of individual welfare changes to a measure of social welfare impacts, ecosystem services face aggregation challenges due to spatial variation in welfare impacts. As previously mentioned, the welfare impacts of different ecosystem services will accrue over different spatial scales. For this reason, care must be taken in identifying the appropriate group of individuals affected by changes in the price or quantity of ecosystem-service provision. Bateman *et al.* (2006) provide a thoughtful discussion of how estimates of individual welfare impact might be obtained to minimize potential biases in the resulting estimates of social welfare impacts. We now turn to a discussion of how observable information can be used to estimate CV and EV, the theoretically accurate measures of welfare in the context of ecosystem services.

Welfare Measures with Marshallian Demand Functions

As a point of origin for this portion of the chapter, we must review the distinction between two popular methods for estimating demand. The ordinary, uncompensated, or Marshallian demand function represents the bundles of goods that a consumer would choose to purchase under each price and income combination, assuming she is able to perfectly solve her utility-maximization problem, as specified in eqn [4]. The Hicksian or compensated measure of demand is derived in a way to isolate the substitution effects of changes in prices from the associated income effects of such changes.

Briefly, a change in the price of a good that is in an individual's optimal consumption bundle (i.e., the good is a component of vector X in expression [10]) has two effects on an individual's consumption choices. First, the change in the price of the good will impact the individual's consumption of that good because the price change will make the good relatively cheaper (for a price reduction) or relatively more expensive (for a price increase) than the other goods in the individual's consumption bundle. This effect of the price change is known as the "substitution effect," because the individual will substitute toward the good whose price has changed from the other goods (for a price reduction) or away from the good whose price has changed toward the other goods (for a price increase). The change in the price of the good will also impact the individual's overall consumption bundle because the price change will either make the consumer more wealthy (for a price reduction) or less wealthy (for a price increase). This effect of the price change is known as the income effect, because the change in the price of the good impacts the income available to be spent on the consumption of goods in the consumption bundle, which will alter total consumption. Hicksian demand is derived in such a way to uniquely identify the substitution effect of a price change by preventing or compensating for any simultaneous income effect.

If we could observe this compensated demand curve, then the calculation of CV or EV would be quite straightforward as previously described. In reality, when a change in the price of a good does not take place, be it an ecosystem service or not, it is not possible to isolate the substitution effects of this change from the income effects. As a result, we cannot generally derive Hicksian demand curves from observed behavior.

When dealing with uncompensated demand functions, which are derived from observed behavior, we are unable to isolate the substitution effects of a change in price from its income effects (Figure 2). As such, we are unable to directly derive accurate estimates of CV and EV from Marshallian demand functions.

The measure of welfare associated with Marshallian demand is known as consumer surplus, CS. Consumer surplus is defined as the area beneath the demand curve and above the market-clearing price from the origin to the market-clearing quantity of consumption for the good in question. Consumer surplus can be affected by both changes in the price of a good as well as changes in the quantity or quality of the good

Figure 2 Compensated and uncompensated demand curves. The compensated demand curve illustrates the relationship between the price of a good and the quantity purchased, holding constant other prices and the individual's utility. The uncompensated demand curve illustrates the relationship between the price of a good and the quantity purchased, assuming that preferences, other prices, and income are held constant. The two curves intersect at point (X', P') because the individual's income at that point is just sufficient to achieve the utility level that is held constant on the compensated demand curve. The compensated demand curve is less responsive to price changes than the uncompensated demand curve, because the income effect, which is controlled for in the compensated demand curve, for normal goods is in the same direction as the substitution effect (i.e., a lower price leads to an increase in quantity purchased both because the good is relatively cheaper than other goods (substitution effect) and because the individual has more wealth to spend at the lower price (income effect)).

provided. Ecosystem services for which markets exist, such as provisioning services, will be able to impact welfare through price changes, whereas services for which there are no markets will have effects on welfare through changes in quality and quantity of the service provided.

The consumer surplus associated with a price change is given by the area beneath the demand curve between the initial and subsequent prices. In other words,

$$CS = - \int_{p_1^0}^{p_1^1} x_1(p_1, \hat{P}, ES, M) dp_1 \quad [17]$$

where x_1 represents the good whose price is changing, $\hat{P}$ represents the vector of prices for all other goods, p_1^0 represents the initial price of the good of interest, p_1^1 represents the price of this good after the price change, and the other variables are as previously defined.

The definition presented in eqn [15] represents the change in consumer surplus associated with a price change in the good of interest. This calculation is common for market goods. Therefore, the calculation in eqn [17] will be of use for provisioning services that undergo a change in market price. However, as we have explained above, the remaining categories of ecosystem services – regulating, cultural, and supporting services – are typically nonmarket goods. For these types of goods, the change of interest is related to the quantity or quality of provision (or both). In the absence of a market, the consumer surplus is defined as the area beneath the

demand curve from the origin up to the observed level of consumption. In other words,

$$CS = - \int_0^{ES_1^1} ES_1(P, \widehat{ES}, M) dES_1 \quad [18]$$

where P represents the vector of prices for all market goods consumed, including provisioning ecosystem services, $\widehat{ES}$ represents the levels of all other ecosystem services consumed, and M represents income. The change in consumer surplus from a change in the quantity of ecosystem-service provision is found by differencing the consumer surplus associated with the original and shifted Marshallian demand curves.

It is clear that the observable (CS) and accurate (CV, EV) measures will differ under many conditions due to the presence of an income effect in observed conditions. Willig (1976) determined the precise differences between the measures, which are driven by the income elasticity of demand for the good in question and the magnitude of consumer surplus as a fraction of total income or expenditures. He concludes that the differences between the welfare measures are relatively small and basically trivial for most realistic conditions. Randall and Stoll (1980) conduct similar analysis for changes in the quantity of the nonmarket good of interest and also determine that consumer surplus is a suitable approximation for CV and EV, though these findings may not be as robust as those of Willig (Hanemann, 1991). Still, these findings are supportive of the use of consumer surplus, which can be empirically derived, as a welfare measure. It should be noted that subsequent efforts have demonstrated practical means of estimating CV and EV directly from observable data (Hausman, 1981; Irvine and Sims, 1998).

Estimating Social Value

As previously described, it is relatively straightforward to derive estimates of the social value of changes in the price or quantity of a good for which a market exists. For many goods, including several ecosystem services, markets do not exist. As a result, the methods previously described, which depend on knowledge of the consumer's demand function for the good of interest, can only be applied using novel methods to identify the demand functions for these goods of interest. The next two sections briefly introduce the methodologies of several different approaches to this problem, which can be broadly grouped into two categories. The first category of approaches is referred to as "revealed preference" because these methods utilize observed behavior to estimate demand for nonmarket goods. The next category is referred to as "stated preference" because these approaches utilize information gleaned from individuals through their responses to surveys, questionnaires, and interviews. Each broad category of approaches to assigning value to nonmarket goods has its benefits and costs, which we will discuss in the next two sections, beginning with revealed-preference methods.

Revealed-Preference Methods

These methods to value nonmarket goods use observed behavior as well as information from other markets to estimate

the demand for a particular nonmarket good. These approaches are referred to as “revealed-preference methods” because an individual’s behavior in existing markets is used to reveal her preference for the nonmarket good being studied. There are two principal revealed-preference methods that are relevant to the topic of ecosystem services: the travel cost method for visits to a recreation site, and hedonic valuation, which uses the property value of a home to estimate the value of changes in ecosystem-service provision. Before introducing these two well-known approaches, we first consider an approach to value ecosystem services that are substitutes for market goods.

The specific revealed-preference method that is most appropriate for use in the valuation of a nonmarket ecosystem service depends on the relationship that exists between the ecosystem service of interest and other goods. In 1974, Karl-Göran Mäler laid the foundation for subsequent efforts to understand how preference information about a public good could be derived from the relationship between the public good and a substitute, market good. The correspondence between the estimated and actual welfare impacts of changes in the amount of ecosystem service provision depend on the substitutability of the ecosystem service and the market good.

Several ecosystem services – such as nutrient and sediment retention, storm-peak mitigation, and possibly air filtration – are perfect substitutes for goods that appear in an individual’s utility function. In this case, where the ecosystem service and the market good are equally well suited to provide a valuable amenity to the individual, it is possible to identify the compensating variation due to a change in the amount of ecosystem-service provision using only information about the price of the substitute market good and the relationship between the market good and the ecosystem service in the production of the valuable amenity.

For example, consider an individual who maximizes utility, $U(X, Z, ES)$, subject to a budget constraint, $M - P_X X - p_Z Z = 0$, where ES is the ecosystem service of interest, Z is the market-good substitute for ES , and X is a composite of all other goods. It is possible to recast this problem as one in which the desired good or service provided by Z or ES , S , directly enters the utility function, so that the previous expression becomes $U(X, S(Z, ES))$. As an example, we can think of ES as the nutrient retention provided by forests and Z as the water filtration provided by a water-treatment plant, where S is the quality of water available for consumption downstream of the forest.

In the case of perfect substitutes, under certain conditions it is possible to identify the compensating variation of a change in the provision of the focal ecosystem service, ES . Let us imagine that the individual currently produces S by purchasing some amount of Z and by enjoying the benefits of the current amount of ecosystem-service provision, ES^0 . If the amount of ecosystem-service provision were to change (from ES^0 to ES^1 , with $ES^1 < ES^0$), and the reduction in the production of S due to the reduction in service provision could be perfectly offset by an increased purchase of Z , then the compensating variation associated with this change in ES is given by the cost of the increased purchase of Z necessary to return the individual to her original consumption of S . Similarly, if

$ES^1 > ES^0$, and some amount of Z is still purchased, then the compensating variation associated with this increase in ES is given by the reduction in cost associated with the production of the initial amount of S .

It is important to note that these results only hold if the individual is using a combination of both ES and Z to produce S before and after the change in ES . If this is true, and the individual is at an interior solution of her constrained utility-maximization problem, then we do not need information about her preferences to estimate the welfare impacts of a change in the focal ecosystem service. So, in the case of perfect substitutes between an ecosystem service and a market good, when the individual is at an interior solution before and after the change in ES , then the amount of money necessary to return the individual to her initial level of S is the same amount of money necessary to return her to her initial level of utility. If the ecosystem service of interest is an imperfect substitute for a market good, then the above result does not hold, though it does serve as a bound on the resulting welfare impact. Bartik (1988) explores the results for imperfect substitutes, and the key points are thoughtfully explained in Section 7.2.2 of Bockstael and Freeman (2005).

The finding that the amount of money required to return an individual to her initial consumption of a good that is equally well provided by an ecosystem service at no cost or a market good does not mean that we can use actual expenditures on the market-good substitute as a direct measure of the value of the ecosystem service. The reason for this point is that the previous finding holds when we are able to isolate the substitution effect of a change in the quantity of ecosystem service provided from the income effect of this change in service provision (i.e., in the context of Hicksian demand). In real-world situations, individuals are unable to isolate the income and substitution effects in this way, meaning that the actual expenditure on the perfect substitute for the ecosystem service following a change in the quantity of ecosystem service available may change even more than expected due to the opportunity to adjust consumption of other goods in the utility function. Bockstael and McConnell (2007) and Bartik (1988) provide further explanations about the relationship between actual expenditures and the actual welfare change as a result of a change in an environmental amenity.

Several notable nonmarket ecosystem services (e.g., nutrient and sediment retention related to water quality, sediment retention above reservoirs, carbon sequestration and storage, storm-peak mitigation) seem to have perfect substitutes among market goods that might allow for valuation estimates based on changes in expenditures on these market goods. Other nonmarket ecosystem services (e.g., recreation, esthetic or cultural benefits, and filtration of air pollutants by vegetation) can be thought of as complements and not substitutes to specific market goods. It is possible to estimate the value of changes in the quantities of these ecosystem services by envisioning them as attributes of heterogeneous goods in order to isolate how changes in the provision of these services impacts the willingness to pay for the complementary good. Two of the best-known revealed-preference valuation approaches, the travel cost method and hedonic price studies of the housing market, are examples of this approach.

The hedonic travel cost approach (Brown and Mendelsohn, 1983) differs from the travel cost procedure (Hotelling, 1949; Clawson, 1959) in that it assigns value to characteristics of destinations as opposed to the different destinations themselves. In this approach, ecosystem services can be thought of as a measure of the quality of a location that could be a destination for recreation. In this context, individuals gain utility from the consumption of a composite market good, the amount of recreation opportunities enjoyed, and the quality of that recreation experience. In this case, there is not a market price for recreation, but the cost of producing the recreation experience can be used as a measure for the price of recreation. This price can be quantified using the costs of transportation and the individual's time, which is estimated using a function of the wage rate. If the transportation and time costs are constant, then the marginal cost of producing the recreation experience can be thought of as the price of the recreation experience. By observing the visitation to sites with different characteristics, as well as the cost of arriving at those sites based on the individual's point of origin, it is possible to estimate the value of changes in the quality of the sites, as measured by changes in provision of ecosystem services. This approach has been used to consider the impact of water quality on recreation (e.g., Phaneuf *et al.*, 2008).

A similar approach can be used to estimate the value of ecosystem services using observed variation in housing prices. In this approach, we assume that the individual's utility is a function of a composite good, as well as the various attributes associated with the individual's choice of housing. The price of any house will be determined by the quantities of the different attributes associated with the given house (e.g., square footage, number of bedrooms, air quality at the site, water quality at a nearby lake, pond, or coast). The hedonic price function maps housing attributes, including the relevant ecosystem service, into market prices for houses. The derivative of this function with respect to any attribute can be interpreted as the marginal implicit price of that attribute. There are some complications with using this approach to determine the welfare impacts of changes in ecosystem service provision at different sites due to the fact that the level of service provision is a choice variable in this approach (see Rosen, 1974; Bartik, 1987; Epple, 1987 for detailed discussion of the causes of this outcome and Bockstael and Freeman (2005) for a thoughtful summary of this issue).

The hedonic property value models have been successfully applied to estimate the value of several different ecosystem services. Leggett and Bockstael (2000) use the hedonic pricing method to determine the impact of water clarity, which is related to nutrient and sediment retention provided by extant habitat around the property, on house prices around Chesapeake Bay. Bin *et al.* (2009), consider the value to society of riparian-zone buffers, through their impacts on water quality, using the hedonic pricing method.

With revealed-preference methods, analysis of actual behavior is used to identify the value of the nonmarket good through its relationship with other goods or services that have observed prices. The hedonic pricing method involves deconstructing the price of a market good and attributing portions of the total value to certain good characteristics (i.e., square footage and number of bedrooms for a house) to identify the value of a particular nonmarket amenity. The

travel cost method can be used to identify the social value of clear water through changes in visitation rates to a river or lake based on cost of travel and the clarity of the water.

For several ecosystem services, observed behavior within markets for related goods can be used to identify the value of these services by understanding how changes in the provision of these services is related to the demand for the related market goods. These revealed-preference approaches require the availability of detailed socioeconomic data on a fine scale (i.e., visitor or parcel-level resolution). One shortcoming of the revealed-preference techniques is that they fail to account for the nonuse value of different nonmarket goods, meaning that they may only provide lower bound estimates of the value of nature, capturing only the values stemming from use of the services provided. Stated-preference methods of nonmarket valuation can be used to identify the full value of such ecosystem services, including nonuse values.

Stated-Preference Methods

Stated-preference methodologies rely on the stated behavior of individuals in a hypothetical setting to identify the value placed on the nonmarket good of interest. Although there are several techniques based on stated preferences, such as conjoint analysis, choice experiments, and contingent valuation, the contingent valuation method is the most commonly applied in the context of ecosystem services (see Farber and Griner (2000) and Powe *et al.* (2005) for examples of the application of conjoint analysis and choice experiments, respectively). In the contingent valuation approach (Mitchell and Carson, 1989; Bateman and Willis, 1999), the researcher uses a survey to elicit information from the respondent about the value that she attaches to a given nonmarket good using her stated willingness to pay (WTP) to experience an increase in the focal good or her stated willingness to accept (WTA) to tolerate a reduction in the focal good.

We can return to the previous definitions of compensating and equivalent variation to illustrate how WTP and WTA are related to these established measures of value. As noted, let the individual's indirect utility, $V()$, be a function of the prices of market goods consumed, P , the amount of ecosystem services consumed, ES , and the individual's income level, M . Consider the situation in which the amount of ecosystem services consumed changes, while the prices of consumed market goods and income are held constant; then the compensating variation, CV , is given by

$$V(P, ES^1, M - CV) = V(P, ES^0, M) \quad [19]$$

and the equivalent variation, EV , is given by

$$V(P, ES^1, M) = V(P, ES^0, M + EV) \quad [20]$$

If $ES^1 > ES^0$ – namely, the change in ecosystem services is viewed as a desirable outcome and an improvement in the amount of service provision – then $CV > 0$ and $EV > 0$. In this case, CV measures the individual's maximum WTP to ensure that the change occurs, and EV represents the individual's minimum WTA to forgo the change. If the change in ecosystem-service provision is viewed as unfavorable, then $CV < 0$

and $EV < 0$, with CV measuring the individual's WTA to tolerate the welfare-reducing change, whereas EV measures the individual's WTP to avoid the change.

The contingent valuation approach involves providing individuals with hypothetical situations in which there is a change in the level of ecosystem services provided (e.g., there is a potential project to restore a wetland that will increase nutrient pollutant retention so that the quality of downstream water bodies will be improved) and then eliciting from those individuals estimates of their WTP or WTA to estimate their perceived value of the focal ecosystem service. This example illustrates the importance of providing very specific information about the change of interest in the survey, particularly in the context of ecosystem services, whose joint provision may potentially result in multiple ecosystem services being impacted within a given hypothetical scenario. In the parenthetical example of restoring a wetland, such action would contribute additional storm-peak mitigation, increased opportunity for bird-watching and other recreational activities, and sediment retention in addition to the retention of nutrient pollutants focused on by the survey, making it difficult to identify the value of the nutrient retention if the survey were not thoughtfully designed. Diamond and Hausman (1994) present some challenges that must be overcome in interpreting responses to contingent valuation surveys as credible estimates of WTP and WTA, whereas Hanemann (1994) provides an overview of how survey design and study methodology can address these challenges.

Carson and Hanemann (2005) provide a clear and thorough discussion of the steps that must be taken to move from the responses elicited through a contingent valuation study to estimates of WTP or WTA for the hypothetical change in the nonmarket good of interest. Briefly, the process entails conceiving of the survey responses as a random variable, which might be the outcome of individuals trying to maximize utility functions that contain a random component, from the perspective of the researcher. Next, a link must be made between the distribution of WTP or WTA that will result from this introduction of randomness and the distribution of responses to the survey. As Carson and Hanemann (2005) note, this linkage depends on the survey format, particularly regarding its use of either open-ended or closed-ended, single-bound discrete-choice formats. In the former case, for a survey of WTP for an increase in the provision of a specific ecosystem service, the respondent would be asked, "How much are you willing to pay for the change from ES^0 to ES^1 (where $ES^1 > ES^0$)?" In the latter case, for the same survey the respondent would be asked, "Would you vote to support the change from ES^0 to ES^1 if it would cost you \$A?" With the open-ended format, the response directly reveals the respondent's value of CV , whereas the closed-ended format response provides an interval in which the respondent's value of CV must lie. To appropriately estimate the relevant measure of value, the researcher must acknowledge the impact of survey design and other assumptions on the relationship between survey response and the distribution of the relevant measure of value. Again, Carson and Hanemann (2005) provide a thoughtful description of these issues.

If thoughtfully designed, contingent valuation surveys can be used to estimate the full value of changes in ecosystem-service provision. However, the challenges of providing

adequate information to ensure that the respondents are assigning value to the specific service of interest are not trivial, and significant thought must go into the methodological development of such studies. Finally, the hypothetical nature of such estimates – meaning that the respondents are not actually being asked to pay the amount of money that they indicate as their WTP in the survey – can be used to question the validity of valuation estimates derived using this approach.

As with the revealed-preference methods of estimating the value of ecosystem-service provision, there are obstacles that must be avoided in applying the contingent valuation methodology. That said, this method has been applied by frequently cited studies to estimate the welfare effects of changes in ecosystem-service provision. Desvousges *et al.* (1987) use this approach to determine the impact of enhanced water quality on recreational experience on a span of river in Pennsylvania. Loomis *et al.* (2000) use contingent valuation to estimate the overall economic impacts of restoration along a stretch of the South Platte River in Colorado, which would affect the provision of several different ecosystem services simultaneously (wastewater dilution, water purification, erosion control, recreation opportunities) as well as habitat for fish and wildlife. Given the shortcomings of both the revealed- and stated-preference approaches, some authors have combined the methodologies with the hope of improving the accuracy of amenity value estimates. These dual approaches have been applied to the value of coastal water quality (Hanley *et al.*, 2003) and to the willingness to pay for recreational trout fishing in Nevada (Englin and Cameron, 1996). While such efforts require additional effort in data collection, such exertion may be rewarded with more precise estimates of amenity value.

Conclusion

As we are increasingly faced with the choice between habitat conversion and conservation, the importance of achieving efficient resource use increases as well. To understand the full benefits and costs of habitat conversion and conservation decisions, we must be able to quantify the value of conserved habitat. This article has reviewed several of the existing methods available for such a task. That said, identifying the value of different resource-use outcomes does not necessarily guarantee that the most desirable outcome will be achieved, or even that there will be agreement about the most desirable outcome. Even as our understanding of ecosystem function and its value to society increases, the issues of equity and political feasibility offer challenges to the successful implementation of policies aimed at achieving efficient resource use.

Glossary

Acid neutralizing capacity (ANC) The amount of strong acid that is required to decrease the pH of water to a defined chemical endpoint. Acid neutralizing capacity is measured in units of $\mu\text{eq l}^{-1}$. It is a measure of the ability of water to neutralize inputs of strong acids.

Acid-sensitive area Characterized by low supply rates of acid neutralizing basic cations. These areas generally occur in high elevation forest regions and are characterized by shallow base poor soil.

Airshed or emission source area An area where emissions of air pollutants originate that are eventually deposited to a position on the Earth's surface.

Atmospheric deposition The process by which materials are deposited from the atmosphere to the Earth's surface.

Bioaccumulation A process by which contaminants, such as mercury, accumulate along food chains.

Methyl Mercury (MHg) The form of mercury largely produced by sulfate and iron reducing bacteria that strongly bioaccumulates along food chains.

Nitrogen saturation A condition where ecosystems, which were previously growth-limited by nitrogen inputs are shifting to limitation by some other resource.

pH The concentration of free hydrogen ion or proton, measured on a logarithmic scale. Thus a solution with a concentration of hydrogen ion of 1 eq l^{-1} has a pH of 0 and is an extremely acidic solution. A hydrogen ion concentration of $0.000,01 \text{ eq l}^{-1}$, typical of a chronically acidic surface water, has a pH of 5. A hydrogen ion concentration of $0.000,000,1 \text{ eq l}^{-1}$ is pH 7, or neutral pH. Note that because pH is a logarithmic scale, as pH values decrease from neutral values, the amount of strong acid required to decrease the pH by a unit value increases greatly. Water with a pH of 5 has 100 times the hydrogen ion concentration as a pH 7; a pH of 4 has 10 times the hydrogen ion concentration of pH 5 or 1000 times the hydrogen ion concentration of a pH 7 solution.

Watershed An area of the landscape, which generally follows topographic features, where incoming precipitation collects and forms water drainage.

Introduction

Detailed studies by scientists for more than five decades have provided considerable insight on how atmospheric deposition alters the structure and function of ecosystems. When it was first identified, acidic deposition was viewed as a simple problem that was limited in scope. Scientists know now that acids, acidifying compounds, mercury, and other substances enter ecosystems from atmospheric deposition and are transported through soil, vegetation, and surface waters, resulting in a range of ecosystem effects (Figure 1).

In this article, information is synthesized on patterns of acidic and mercury deposition, and the effects of atmospheric sulfur, nitrogen, and mercury deposition on sensitive forest, and freshwater resources.

Emissions of Acidifying Substances and Acidic Deposition

Acidic deposition is largely comprised of sulfuric and nitric acid derived from sulfur dioxide and nitrogen oxides emissions, respectively, and ammonium resulting from emissions of ammonia. Sulfur dioxide and nitrogen oxides, originating from human activities, are largely emitted to the atmosphere by the burning of fossil fuels, while ammonia is largely the result of agricultural activities (Driscoll *et al.*, 2001a, 2003). While there are also natural sources of these materials, they tend to be small compared to human sources in developed regions of North America, Europe, and Asia. Once these compounds enter an ecosystem, they can acidify soil and surface waters, bringing about a series of ecological changes.

Figure 1 Conceptual diagram of acidic deposition. Acidic deposition is a complex environmental problem that originates with combustion of fossil fuels and leads to deposition of acids and results in a series of ecological effects (Driscoll *et al.*, 2001b). Courtesy of the Hubbard Brook Research Foundation.

The term acidic deposition or acidifying deposition encompasses all of the forms of these compounds that are transported from the atmosphere to the Earth, including gases, particles, rain, snow, clouds, and fog. Acidic deposition occurs as wet deposition: as rain, snow, sleet, or hail; as dry deposition, as particles or vapor; or as cloud or fog deposition, which is more common at high elevations or in coastal areas. Wet deposition is fairly well characterized by monitoring at about 250 National Atmospheric Deposition Programs (NADP; <http://nadp.sws.uiuc.edu/>) in the US. In contrast dry deposition is highly dependent on meteorological condition and vegetation characteristics, which can vary markedly over short distances in complex terrains. As a result dry deposition is generally poorly characterized and highly uncertain. Dry deposition is estimated through the Clean Air Status and Trends Network (CASTNet; <http://www.epa.gov/castnet/>), which includes about 100 sites in the US.

Sulfuric and nitric acids lower the pH of rain, snow, soil, lakes, and streams. Areas experiencing elevated acidic deposition include eastern North America (Figure 2), the western US, Europe, and Asia. In 2007–2009, wet deposition (i.e., deposition from forms of precipitation such as rain, snow, sleet, and hail) in acid-sensitive regions of the eastern US had average pH values of 4.4–5.0, which is about two to five times more acidic than background conditions.

Acidic deposition trends in the eastern US and Europe mirror emission trends in the atmospheric source area or airshed. Long-term data from across the eastern US and Europe show declining concentrations of sulfate in wet deposition since the mid-1970s, coincident with decreases in sulfur dioxide emissions. Based on these long-term data, a strong positive correlation exists between sulfur dioxide emissions in the source area and sulfate concentrations in wet deposition. It is expected that the sulfate concentration of wet deposition will decrease (or increase) in an approximately linear response to the decrease (or increase) of sulfur dioxide

emissions in the atmospheric source area (Driscoll *et al.*, 2001a). These observations strongly suggest a cause and effect relationship between emissions of sulfur dioxide and deposition of sulfate. A similar relationship is starting to become evident between emissions of nitrogen oxides and wet deposition of nitrate. This relationship for nitrate is not as strong as the relationship for sulfur because emissions of nitrogen oxides were relatively constant through the 1980s and 1990s. However, in the US recent decreases in emissions of nitrogen oxides largely from electric utilities have resulted in decreases in atmospheric deposition of nitrate (Butler *et al.*, 2003).

Mercury Emissions and Deposition

Globally mercury is released to the environment in several ways, but the dominant pathway is airborne emissions and deposition. Fossil fuel combustion, and metal, gold and cement production rank among the highest human mercury emission sources worldwide (AMAP/UNEP, 2008). The largest single source of mercury emissions in the US is coal-fired power plants (Driscoll *et al.*, 2007a; <http://www.epa.gov/ttn/chief/net/2005inventory.html>).

The total amount of mercury released to the atmosphere worldwide is approximately 14,520,000 lbs (7,260 short tons), of which two-thirds originates from anthropogenic sources (Mason and Sheu, 2002). Mercury is a naturally occurring substance and about one-third of mercury emissions are from geologically generated sources. While overall mercury emissions in the US decreased from 490,000 lbs (245 tons) in 1990 to 228,000 lbs (107 tons) in 2005, emissions from coal-fired power plants did not change appreciably during that period and are now the largest source in the US.

One key to understanding where mercury deposits following release to the atmosphere is the nature of mercury emissions and deposition pathways. Mercury is emitted to the atmosphere in several different forms: elemental mercury,

Figure 2 Map of wet sulfate, nitrate, and ammonium deposition for the US for 2009.

Figure 3 Different forms of mercury can travel varying distances before depositing to foliage, surface waters, and the land. Also, certain conditions enhance mercury deposition (Driscoll *et al.*, 2007b). Courtesy of the Hubbard Brook Research Foundation.

reactive gaseous mercury, and particulate mercury (Figure 3). The latter two forms together are known as oxidized (or ionic) mercury. Elemental mercury is a relatively inert gas that does not readily dissolve in water. Therefore, it generally travels farther in the atmosphere than oxidized mercury; it is truly a global contaminant with a residence time in the atmosphere of 0.5–2 years. Oxidized mercury is more chemically reactive and soluble in water than elemental

mercury, and therefore generally deposits more rapidly, hours to days following emissions, and closer to the source (Driscoll *et al.*, 2007a). Elemental mercury can be converted to oxidized mercury in the atmosphere and deposited to the Earth's surface, and oxidized mercury can be converted to reduced mercury. Note this latter process largely occurs at the Earth's surface and is referred to as evasion or re-emission of mercury. Re-emission is an important process by which

previously deposited mercury can be emitted back to the atmosphere.

Scientists have identified pathways for direct deposition of elemental mercury. Trees and other vegetation take up elemental mercury by scavenging it out of the atmosphere with their rough leaf surfaces, or through gas exchange in pores on the leaf surface known as stomates (Driscoll *et al.*, 2007a). In forests of the Northeast, estimates suggest that up to 70% of total mercury deposition may occur through this “dry deposition” process (Driscoll *et al.*, 2007a). Based on what is known about how the various forms of mercury are transported or converted in the atmosphere, and the importance of dry deposition, it can be concluded that all forms of mercury (oxidized and elemental) may deposit locally or regionally.

Scientists use several methods to estimate mercury deposition from the atmosphere to the land surface. Like acidic deposition, mercury deposition occurs as both wet and dry deposition. Wet deposition in rain or snow is measured at a network of approximately 90 stations in North America known as the Mercury Deposition Network (MDN; <http://nadp.sws.uiuc.edu/mdn/>). MDN is part of the National Atmospheric Deposition Program (NADP). Dry deposition is not systematically measured in the US due to technical challenges, but it is estimated using a variety of approaches.

Effects of Acidic Deposition on Forest Ecosystems

In acid-sensitive regions, acidic deposition alters soils, stresses forest vegetation, acidifies lakes and streams, and harms fish and other aquatic life. These effects can interfere with important ecosystem functions and services such as forest and aquatic biodiversity and productivity, and soil and water quality. Years of acidic deposition have also made many ecosystems increasingly sensitive to continuing pollution. Moreover, the same pollutants that cause acidic deposition contribute to a wide array of other important environmental issues at local, regional, and global scales (Table 1).

Effects of Acidic Deposition on Forest Soils

Research has shown that acidic deposition has chemically altered soils with serious consequences for acid-sensitive

ecosystems. Soils compromised by acidic deposition lose their ability to neutralize continuing inputs of strong acids, provide poorer growing conditions for plants, and extend the time needed for ecosystems to recover from acidic deposition.

Acidic deposition has altered and continues to alter soils in acid-sensitive regions in three important ways. Acidic deposition depletes available calcium and magnesium from exchange sites in soil; facilitates the mobilization of dissolved inorganic aluminum into soil water; and increases the accumulation of sulfur and nitrogen in soil.

Loss of Calcium and Other Nutrient Cations

The cycling of calcium and other nutrient cations (magnesium, potassium) in forest ecosystems involves the inputs and losses of these materials (Figure 4). For most forest ecosystems, the supply of calcium and other nutrient cations largely occurs by weathering (i.e., the breakdown of rocks and minerals in soil). Calcium and other nutrient cations may also enter forests by atmospheric deposition, although this pathway is generally much smaller than weathering. Losses largely occur by vegetation uptake and drainage waters. An important pool of ecosystem calcium and nutrient cations is the soil available pool or the soil cation exchange complex. Plants are generally able to utilize this source of nutrients. Forest ecosystems that are naturally sensitive to acidic deposition are generally characterized by low rates of weathering and generally low quantities of available nutrient cations. Under conditions of elevated inputs of acidic deposition and subsequent transport of sulfate and nitrate in drainage waters, nutrient cations are displaced from available pools and leached from soil. This condition is not problematic for areas with high weathering rates and high pools of available nutrient cations. However, in acid-sensitive areas with shallow soil and which contain minerals that are resistant to weathering, the enhanced loss of calcium and other nutrient cations can result in a depletion of soil available pools. Acid sensitive conditions generally occur in high elevation often forested regions with acidic soils that are underlain by surficial materials or bedrock that are resistant to weathering; for the US acid sensitive regions are shown in Figure 5.

Over the last century, acidic deposition has accelerated the loss of large amounts of available calcium from acid-sensitive soil in acid-sensitive areas. Depletion occurs when nutrient cations are displaced from the soil by acidic deposition at a rate faster than they can be replenished by the slow breakdown of rocks and minerals or the deposition of nutrient cations from the atmosphere. This depletion of nutrient cations fundamentally alters soil processes, compromises the nutrition of some trees, and hinders the capacity for sensitive soils to ultimately recover. For example, more than half of the available calcium has been lost from soil at the Hubbard Brook Experimental Forest, New Hampshire over the past 60 years (Likens *et al.*, 1996). Note that while acidic deposition to acid-sensitive areas is decreasing in North America and Europe, and there is some associated recovery of the acid neutralizing capacity (ANC) of surface waters (*see* Surface Water Acidification), it appears that forest soils continue to exhibit net depletion of exchangeable nutrient cations.

Table 1 The links between sulfur dioxide and nitrogen oxide emissions, acidic deposition, and other important environmental issues

<i>Problem</i>	<i>Linkage to acid deposition</i>
Coastal, terrestrial, and freshwater eutrophication	Atmospheric deposition adds nitrogen to ecosystems, increasing productivity and altering species richness.
Mercury	Surface water acidification increases mercury accumulation in fish.
Visibility	Sulfate aerosols diminish visibility and views.
Tropospheric ozone	Emissions of nitrogen oxides contribute to the formation of ozone.

Figure 4 Conceptual diagram illustrating the inputs and losses of calcium and other nutrient cations for forest ecosystems. Ecosystems with low weathering rates have low supplies of calcium and other nutrient cations available to soil and trees. High inputs of acidic deposition increase the leaching of calcium and other nutrient cations from soil. In acid-sensitive regions with low weathering rates, inputs of acidic deposition can deplete soil pools of available calcium and other nutrient cations and limit quantities available for tree growth.

Mobilization of Aluminum

Aluminum is often released from soil to soil water, lakes, and streams in forested regions with high acidic deposition, low stores of available calcium, and high soil acidity. One of the most significant ecological effects of acidic deposition is the mobilization of aluminum from soil and a shift in the form of dissolved aluminum in water from nontoxic organic forms to highly toxic inorganic forms.

Concentrations of aluminum increase markedly with decreases in pH, particularly the toxic inorganic forms of aluminum. It is evident that concentrations of aluminum increase exponentially when surface water pH decreases below 6.0. Aluminum concentrations are thought to be ecologically significant when they increase to values above $2 \mu\text{mol l}^{-1}$ (Driscoll *et al.*, 2001a). This condition can occur when pH values decrease below 6.0.

High concentrations of dissolved inorganic aluminum can be toxic to plants, fish, and other organisms. Concentrations of dissolved inorganic aluminum in streams in acid sensitive areas of eastern North America and areas of Europe are often above levels considered toxic to fish, and much greater than concentrations observed in forest watersheds that receive low inputs of acidic deposition.

Accumulation of Sulfur and Nitrogen

Increases in atmospheric sulfur and nitrogen deposition will increase the quantities of these elements that accumulate in soil and ecosystems. This perturbation can have both positive and negative effects. The accumulation of sulfur in soil from atmospheric deposition occurs through adsorption of sulfate on mineral soil surfaces and increases inorganic sulfur through the accumulation of soil organic matter. This increase in soil sulfur will have limited direct adverse effects on soil quality, but following decreases in atmospheric sulfur deposition will release sulfate from soil to surface waters delaying recovery from acidic deposition. This process is particularly prominent in regions

with unglaciated soil that have a large capacity to retain sulfate, such as the southeastern US (Galloway *et al.*, 1983).

Likewise, increased deposition of nitrogen increases ecosystem retention of nitrogen. Increases in nitrogen loading likely accelerate a process known as “nitrogen saturation” (Aber *et al.*, 1989). Nitrogen saturation is a condition where ecosystems, which were previously growth-limited by nitrogen inputs are shifting to limitation by some other resource. Nitrogen saturation results in changes in the structure and function of ecosystems and increases leaching losses of nitrate to surface waters contributing to acidification.

Elevated atmospheric nitrogen deposition can also have beneficial effects on ecosystems. As mentioned, nitrogen is generally the growth-limiting nutrient to terrestrial ecosystems. Increases in nitrogen loading should be accompanied by an increase in net ecosystem production and biomass. This perturbation enhances sequestration of carbon from the atmosphere.

Effects of Acidic Deposition on Trees

Acidic deposition has contributed to the decline of red spruce and sugar maple trees in the eastern US (Figure 6), and shifts in the distribution of tree species. Symptoms of tree decline include poor condition of the canopy, reduced growth, and unusually high levels of mortality. Declines of red spruce and sugar maple in the northeastern US have occurred during the past five decades. Factors associated with declines of both species have been studied and include important links to acidic deposition.

Red Spruce

Since the 1960s, more than half of large canopy red spruce in the Adirondack Mountains of New York and the Green Mountains of Vermont and approximately one quarter of large canopy red spruce in the White Mountains of New Hampshire have died (DeHayes *et al.*, 1999). Significant growth declines

Figure 5 Map showing areas of the US with low values of acid neutralizing capacity in surface waters that are potentially sensitive to acidic deposition (Eilers and Selle, 1991).

Figure 6 Conceptual diagram illustrating the mechanisms by which acidic deposition impacts red spruce and sugar maple (Driscoll *et al.*, 2001b). Acidic deposition impacts red spruce through loss of membrane calcium due to direct leaching from foliage or reduced uptake of calcium from soil. The loss of membrane calcium makes red spruce more susceptible to winter injury. Acidic deposition results in loss of soil available calcium and magnesium and less uptake by sugar maple. This condition may make sugar maple more susceptible to insect or drought stress. Courtesy of the Hubbard Brook Research Foundation.

and winter injury to red spruce have been observed throughout its range. Acidic deposition is a major cause of red spruce decline at high elevations in the Northeast.

Red spruce decline occurs by both direct and indirect effects of acidic deposition. Direct effects include the leaching of calcium from leaves and needles of trees (i.e., foliage), whereas indirect effects refer to acidification of the underlying soil chemistry.

The decline of red spruce is linked to the leaching of calcium from cell membranes in spruce needles by acid mist or fog. The loss of calcium renders the needles more susceptible to freezing damage, thereby decreasing the tolerance of trees to low temperatures and increasing the occurrence of winter injury and subsequent tree damage or death (DeHayes *et al.*, 1999). In addition, elevated aluminum concentrations in the soil may limit the ability of red spruce to take up water and nutrients through its roots. Water and nutrient deficiencies can lower the tolerance of trees to other environmental stresses and cause decline.

Sugar Maple

The decline of sugar maple has been studied in the eastern US since the 1950s. Extensive mortality among sugar maples appears to have resulted from deficiencies of nutrient cations (calcium, magnesium), coupled with other stresses such as insect defoliation or drought (Horsley *et al.*, 2000). The probability of decreases in the vigor of the sugar maple canopy or incidence of tree death increases on sites where the supply

of calcium and magnesium to soil and foliage are lowest and stress from insect defoliation and drought is high. Low levels of nutrient cations can cause a nutrient imbalance and reduce the ability of a tree to respond to stresses such as insect infestation and drought.

Shifts in the Distribution of Tree Species with Increases in Atmospheric Nitrogen Deposition

Thomas *et al.* (2010) observed differential changes (both positive and negative responses) in annual aboveground carbon increment and 5-year survival rate as a function of total (wet + dry) inorganic nitrogen deposition for the 24 most common tree species in the northeastern US. Tree species such as red pine, red spruce, and white cedar show declining growth under elevated atmospheric nitrogen deposition, while 11 species show a positive growth response. This research suggests that different tree species are responding differently to increases in atmospheric nitrogen deposition and with ongoing elevated deposition there will be shifts in the species abundance.

Effects of Acidic and Mercury Deposition on Freshwater Aquatic Ecosystems

Surface Water Acidification

Acidic deposition degrades surface water quality by lowering pH (i.e., increasing acidity); decreasing ANC; and increasing

dissolved inorganic aluminum concentrations. While sulfate and to a lesser extent nitrate concentrations in lakes and streams have decreased in eastern North America and Europe over the last 20 years, they remain high compared to background conditions (e.g., approximately $20 \mu\text{eq l}^{-1}$ for sulfate and $1 \mu\text{mol l}^{-1}$ for nitrate). Moreover, improvement in other chemical conditions in many lakes and streams in acid-impacted regions has been limited.

Acidification of surface waters due to elevated inputs of acidic deposition have been reported in many acid-sensitive areas receiving elevated inputs of acidic deposition, including Great Britain, Nordic countries, Northern, Central and Eastern Europe, southwestern China, southeastern Canada, the northeastern US, the Upper Midwest and the Appalachian mountain region of the US. Large portions of the high elevation western US are also potentially sensitive to acidic deposition, however, atmospheric deposition to this region is relatively low. Concern over acidic deposition in the mountain West of the US has been overshadowed by potential effects of elevated nitrogen deposition, including eutrophication of naturally nitrogen-limited lakes (Fenn *et al.*, 2003).

To illustrate the regional impacts of acidic deposition, a comprehensive survey of lakes greater than 0.2 ha in surface area in the Adirondack region of New York was conducted in the mid-1980s to obtain detailed information on the acid-base status of waters in this region. Of the 1469 lakes surveyed, 24% had summer pH values below 5.0. Also 27% of the lakes surveyed were chronically acidic (i.e., ANC less than $0 \mu\text{eq l}^{-1}$) and an additional 21% were susceptible to episodic, or short-term acidification (i.e., ANC between 0 and $50 \mu\text{eq l}^{-1}$).

Seasonal acidification is the periodic increase in acidity and the corresponding decrease in pH and ANC in streams and lakes, which generally occurs during the higher flow fall, winter and spring periods. Episodic acidification is caused by the sudden pulse of acids and a dilution of base cations (i.e., calcium, magnesium, sodium, potassium) due to spring snowmelt and large rain events generally in the spring and fall. Acidic episodes are when the surface water ANC decreases to near or below $0 \mu\text{eq l}^{-1}$ during events. Increases in nitrate are often important to the occurrence of acidic episodes. These conditions tend to occur when trees are dormant and therefore retain less nitrogen. At some sites short-term increases in sulfate and naturally occurring organic acids can also contribute to episodic acidification. Episodic acidification often coincides with pulsed increases in concentrations of dissolved inorganic aluminum. Short-term increases in acid inputs to surface waters can reach levels that are lethal to fish and other aquatic organisms. All of the acid-sensitive and acid-impacted regions discussed in this article have documented effects associated with episodic acidification.

Trends in surface water chemistry in Europe and eastern North America indicate that recovery of aquatic ecosystems impacted by acidic deposition is occurring over a large geographic scale since the early 1980s. Some regions are showing rather marked recovery, while others exhibit low or non-existent increases in ANC. Based on long-term monitoring, virtually all surface waters impacted by acidic deposition in Europe and eastern North America exhibit decreases in sulfate concentrations. This pattern is consistent with decreases in

emissions of sulfur dioxide and atmospheric sulfate deposition. The exception to this pattern is streams in the unglaciated southeastern US. Watersheds in the southeastern US exhibit strong adsorption of atmospheric sulfate deposition by highly weathered soils. In Europe, the most marked decreases in surface water sulfate have occurred in the Czech Republic and Slovakia, regions that experienced historically very high rates of atmospheric sulfate deposition (Evans *et al.*, 2001). More than half of the surface waters monitored in Europe are showing increases in ANC. The rate of ANC increase in Europe is relatively high. This pattern is, in part, not only due to the relatively high rates of sulfate decreases, but also to the fact that decreases in base cations are occurring at about half the rate of the decreases in sulfate plus nitrate, allowing for relatively large rates of ANC increases. In contrast, in the US only three regions are showing statistically significant increases in ANC; lakes in the Adirondacks and Upper Midwest and streams in the Northern Appalachian Plateau (Kahl *et al.*, 2004). In the US, decreases in the sum of base cations closely correspond to decreases in sulfate plus nitrate, limiting rates of ANC increase.

Three factors account for the relatively slow chemical recovery of the water quality of acid-impacted surface waters, despite the decreased deposition of sulfate. First, levels of acid-neutralizing base cations in streams have decreased markedly due to a loss of base cations from the soil and, to a lesser extent, a decrease in atmospheric inputs of base cations. Second, conditions of nitrogen saturation and nitrate leaching have contributed to the acidification of surface waters in many acid-impacted regions. Finally, sulfur has accumulated in the soil and is now being released to surface water as sulfate, even though sulfate deposition has decreased. It appears the only approach to accelerate the recovery of acid-impacted lakes is to make additional cuts in emissions of sulfur dioxide and nitrogen oxides.

The modest decreases in sulfate concentrations and increases in pH and ANC exhibited in some surface waters is an encouraging sign that impacted ecosystems are responding to emission controls and moving toward chemical recovery. Nevertheless, the magnitude of these changes is small compared to the magnitude of increases in sulfate and the decreases in acid neutralizing capacity that have occurred in acid-impacted areas following historical increases in acidic deposition. Moreover, as discussed above, in many acid-sensitive regions soils continue to acidify despite decreases in acidic deposition (*see* Loss of Calcium and Other Nutrient Cations).

Response of Aquatic Biota to Acidification of Surface Waters by Acidic Deposition

Decreases in pH and elevated concentrations of dissolved inorganic aluminum have resulted in physiological changes to organisms, direct mortality of sensitive life history stages, and diminished the species diversity and abundance of aquatic life in many streams and lakes in acid-impacted areas. Fish have received the most attention to date, but entire food webs are often adversely affected.

Decreases in pH and increases in aluminum concentrations have diminished the species diversity and abundance of plankton, invertebrates, and fish in acid-impacted surface

waters. A detailed summary of the response of aquatic biota to the acidification of surface waters is provided in **Table 2**.

In the Adirondacks, a significant positive relationship exists between the pH and ANC levels in lakes and the number of fish species present in those lakes (**Figure 7**). Surveys of 1469 Adirondack lakes conducted in 1984 and 1987 show that 24 percent of lakes (i.e., 346) in this region do not support fish. These lakes had consistently lower pH and ANC, and higher concentrations of aluminum than lakes that contained one or more species of fish. Experimental studies and field observations demonstrate that even acid-tolerant fish species such as brook trout have been eliminated from some waters.

Similar relationships are evident in surface waters in acid-impacted regions throughout the world. Studies demonstrate effects of acidic deposition on fish at three ecosystem levels:

- Effects on single organisms (condition factor – the relationship between the weight and the length of a fish). Fish condition factor is related to several chemical indicators of acid-base status, including minimum pH. This analysis suggests that fish in acidic streams use more energy to maintain internal chemistry that would otherwise be used for growth.
- Population-level effects (increased mortality). Bioassay experiments show greater mortality in chronically acidic streams than in high acid neutralizing capacity streams. Eggs and fry are sensitive life history stages for fish.
- Community-level effects (reduced species richness). The species richness of fish and other aquatic organisms decreases with decreasing acid neutralizing capacity and pH.

Although chronically high acid levels stress aquatic life, acidic episodes are particularly harmful because abrupt, large changes in water chemistry allow fish few areas of refuge. High concentrations of dissolved inorganic aluminum are directly toxic to fish and pulses of aluminum during acid episodes are a primary cause of fish mortality. High acidity and aluminum concentrations disrupt the salt and water balance of blood in a fish, causing red blood cells to rupture and blood viscosity to increase. Studies show that the viscous blood strains the heart of a fish, resulting in mortality.

Acid neutralizing capacity is commonly used to assess the acid-base status of surface waters. The US Environmental Protection Agency (USEPA, 2009) suggested five ANC classes coinciding with levels of concern for surface waters with respect to effects of acidic deposition that are linked to effects on aquatic biota: acute ($\text{ANC} < 0 \mu\text{eq l}^{-1}$), representing chronically acidic conditions; severe ($\text{ANC } 0\text{--}20 \mu\text{eq l}^{-1}$), waters that experience acidic conditions and acidic episodes; elevated ($\text{ANC } 20\text{--}50 \mu\text{eq l}^{-1}$), waters that exhibit episodic acidification to low ANC values; moderate ($\text{ANC } 50\text{--}100 \mu\text{eq l}^{-1}$), waters that are moderately sensitive to episodic acidification; and low ($\text{ANC} > 100 \mu\text{eq l}^{-1}$), waters with little sensitivity to acidic deposition (USEPA, 2009; **Figure 7**).

Mercury Contamination

The deposition of mercury onto the landscape is just one step in the complex suite of transformations of mercury from an inert element in the Earth's crust to a harmful contaminant in fish and wildlife (**Figure 8**). Most mercury entering the environment

Table 2 Biological effects of surface water acidification in North America

<i>pH decrease</i>	<i>General biological effects</i>
6.5–6.0	Small decrease in species richness of phytoplankton, zooplankton, and benthic invertebrate communities resulting from the loss of a few highly acid-sensitive species, but no measurable change in total community abundance or production. Some adverse effects (decreased reproductive success) may occur for highly acid-sensitive species (e.g., fathead minnow, striped bass).
6.0–5.5	Loss of sensitive species of minnow and dace, such as blacknose dace and fathead minnow; in some waters decreased reproductive success of lake trout and walleye, which are important sport fish species in some areas. Visual accumulations of filamentous green algae in the littoral zone of many lakes, in some streams. Distinct decrease in the species richness and change in species composition of the phytoplankton, zooplankton, and benthic invertebrate communities, although little if any change in total community biomass or production.
5.5–5.0	Loss of several important sport fish species, including lake trout, walleye, rainbow trout, and smallmouth bass; as well as additional nongame species such as creek chub. Further increase in the extent and abundance of filamentous green algae in lake littoral areas and streams. Continued shift in the species composition and decline in species richness of the phytoplankton, periphyton, zooplankton, and benthic invertebrate communities; decrease in the total abundance and biomass of benthic invertebrates and zooplankton may occur in some waters. Loss of several additional invertebrate species common in oligotrophic waters, including <i>Daphnia galeata mendotae</i> , <i>Diaphanosoma leuchtenbergianum</i> , <i>Asplanchna priodonta</i> ; all snails, most species of clams, and many species of mayflies, stoneflies, and other benthic invertebrates. Inhibition of nitrification.
5.0–4.5	Loss of most fish species, including most important sport fish species such as brook trout and Atlantic salmon; few fish species able to survive and reproduce below pH 4.5 (e.g., central mudminnow, yellow perch, and in some waters, largemouth bass). Measurable decline in the whole-system rates of decomposition of some forms of organic matter, potentially resulting in decreased rates of nutrient cycling. Substantial decrease in the number of species of zooplankton and benthic invertebrates and further decline in the species richness of the phytoplankton and periphyton communities; measurable decrease in the total community biomass of zooplankton and benthic invertebrates in most waters. Loss of zooplankton species such as <i>Tropocyclops prasinus mexicanus</i> , <i>Leptodora kindtii</i> , and <i>Conochilus unicornis</i> ; and benthic invertebrate species, including all clams and many insects and crustaceans. Reproductive failure of some acid-sensitive species of amphibians such as spotted salamanders, Jefferson salamanders, and the leopard frog.

Figure 7 The mean number of fish species for lakes with different values of acid neutralizing capacity in the Adirondack region of New York. Also shown are the various sensitivity classes for aquatic biota.

Figure 8 Conceptual diagram of atmospheric mercury deposition, transport, and transformations through a watershed-lake ecosystem, bioaccumulation along the food chain and exposure to humans and wildlife (Driscoll *et al.*, 2007b). Courtesy of the Hubbard Brook Research Foundation.

from atmospheric deposition occurs as inorganic mercury that poses no direct health risk. However, as this relatively benign form of mercury is transported with water through the watershed, it comes into contact with bacteria that process sulfate or iron in wetlands and lake or river sediments, and can be converted to the more bioavailable methyl mercury form. Relatively low concentrations of methyl mercury then bioaccumulate

through the aquatic food chain and can reach very high concentrations in fish (Figure 9). Data show that methyl mercury concentrations increase nearly 10 million times as it is transferred from water to algae, invertebrates, small fish, larger fish, and to birds and other wildlife (Figure 10).

Much of the mercury entering the environment from atmospheric deposition is retained in soil and sediments. This

Figure 9 Mercury measurements in 13 of the most abundant freshwater fish species in eastern North America. Note 10 of 13 species exceed the EPA human health criterion of $0.3 \mu\text{g g}^{-1}$ (w/w; Driscoll *et al.*, 2007b). Courtesy of the Hubbard Brook Research Foundation.

Figure 10 Concentrations and ranges of mercury in water and aquatic biota in eastern North America. Also shown are the percentages of total mercury that occurs as methyl mercury.

mercury represents a long-term legacy of atmospheric emissions and deposition. The extent to which this mercury is transported from soil to downstream surface waters is unclear, although a fraction is transported particularly during high flow events. Nevertheless, the mobilization of this legacy mercury would delay the recovery of contaminated ecosystems after the implementation of controls on mercury emissions.

Sensitivity to atmospheric mercury deposition refers to two processes that occur after mercury is deposited to the landscape: methyl mercury production and methyl mercury bioaccumulation (or transfer along the food chain). The rate at which ionic mercury is converted to methyl mercury and supplied to surface waters varies from watershed to watershed. The following are important watershed characteristics that

influence methyl mercury production and transport: shallow hydrologic flowpaths, abundant shoreline wetlands, small watershed to lake area ratio, land cover (e.g., substantial wetlands and forestlands), and inputs of sulfate such as from acidic deposition (Driscoll *et al.*, 2007a). Where these conditions prevail, methyl mercury production and supply to surface waters are expected to be high.

The second component of sensitivity is “surface water sensitivity”, or the ability of a lake or rivers to bioaccumulate methyl mercury to high levels in fish and wildlife. Several key factors controlling surface water sensitivity are: nutrient levels, food chain length, and surface water acidity.

Exposure to mercury largely occurs through consumption of fish or other food sources that contain elevated

concentrations of mercury (general methyl mercury; Driscoll *et al.*, 2007a). Mercury contamination is widespread. In the US, all 50 states have mercury advisories. These advisories cover 13 million lake acres and 764,000 river miles (Driscoll *et al.*, 2007a).

It has been estimated that between 300,000 and 400,000 children are born each year in the US at risk for impairment due to mercury poisoning as the result of fish consumption by the mother (Mahaffey *et al.*, 2004). Six percent of US women of childbearing age have blood mercury in excess of values deemed safe by the US Environmental Protection Agency (Schober *et al.*, 2003). Children exposed to high concentrations of methyl mercury can experience decreased ability to perform in school, declines in visual and spatial functions, delays in ability to recall and process information, and a general diminishment in intelligence. Several studies have also pointed to a connection between mercury exposure and cardiovascular disease in men. Elevated mercury in fish has been linked to decreased spawning success. In fish-eating wildlife, mercury exposure is associated with reduced reproductive success, impaired motor skills and death (Driscoll *et al.*, 2007a).

Recently, scientists have also shown that methyl mercury accumulates along the terrestrial food chain. Elevated concentrations have been observed in song birds in habitats at high elevations and in wetlands (Rimmer *et al.*, 2005).

Linkages among Acidic Deposition, Surface Water Acidification and Fish Mercury Concentrations

Several research studies indicate a linkage between acidic deposition and mercury concentrations in fish. Atmospheric deposition of sulfate associated with sulfur dioxide emissions provides a necessary substrate for methylating bacteria. Methylating bacteria convert ionic mercury into methyl mercury, the form of mercury, which bioaccumulates in fish and other wildlife.

Researchers have shown that experimental addition of sulfate to wetlands increase methylation and increase export of methyl mercury (Branfireun *et al.*, 1999). These studies infer that increasing sulfur dioxide emissions and sulfate deposition would result in increases in methyl mercury in the fish of receiving waters, or by analogy decreases in sulfate inputs would decrease fish mercury. In this regard, Drevnick *et al.* (2007) showed that decreases in fish mercury concentrations in Isle Royal in Lake Superior were coupled with historical decreases in atmospheric sulfate deposition.

Studies across eastern North America have shown that many lakes and reservoirs have elevated concentrations of mercury in fish tissue (Driscoll *et al.*, 2007a; Kamman *et al.*, 2005). Many of these surface waters have fish mercury content above the US Environmental Protection Agency health advisory action level of $0.3 \mu\text{g g}^{-1}$ (Figure 9). In addition, numerous studies across eastern North America have reported increases in fish mercury concentrations with decreases in surface water pH (Driscoll *et al.*, 2007a).

Hrabik and Watras (2002) used observations from experimentally acidified Little Rock Lake, Wisconsin, and reference data to examine the relative contribution of atmospheric mercury deposition and acidic deposition in regulating changes in

fish mercury concentrations. They observed that decreases in fish mercury in an experimentally deacidified basin exceeded those in the reference basin. Specifically, they found that approximately one-half of the changes in fish mercury concentrations over a six-year period could be attributed to deacidification (Hrabik and Watras, 2002). This study suggests that acidification of lakes by acidic deposition has enhanced fish mercury concentrations and that concentrations of mercury in fish may decrease in response to decreasing acidic deposition.

Glossary

Acidification The process of soil or water becoming more acidic, with a loss of base cations (calcium, magnesium, potassium) and an increase in hydrogen and aluminum ion concentrations.

Acidophytic Species of plant adapted to grow on an acidic substrate.

Acute toxicity A damaging effect caused by a single short period of exposure to high concentrations of a pollutant.

Bioaccumulation The accumulation of toxic substances within an organism, primarily due to the rate of uptake by the organism being significantly greater than the loss rate.

Chronic toxicity A damaging effect caused by a long period of exposure to low or moderate concentrations of a pollutant.

Deposition The rate of influx of a substance from the atmosphere, usually expressed as mass per unit area of ground.

Detoxification Reduction in the toxic effect of a pollutant by its chemical or biological transformation to another less toxic chemical.

Eutrophication The enhancement of nutrient levels within an ecosystem, due to direct discharge into waters or aerial deposition to terrestrial systems.

Nitrophytic Species of plants that either tolerate or require high levels of nutrients, and in particular nitrogen.

Ombrotrophic Ecosystems or plant species only receiving nutrients in precipitation.

Phytotoxic Harmful to plants.

Air pollution results from emissions from a range of sources, including industry, power generation, transport, and domestic sources. Its local impacts on biodiversity can be dramatic close to large point sources of emissions, but significant impacts on biodiversity over much wider areas can also result from the long-range transport of pollutants. This article provides a brief description of air pollution sources and pathways, and then considers the major mechanisms by which air pollution can affect biodiversity. It then describes the evidence of such impacts in the field, focusing on a limited number of case studies. It finally considers the issues connected with establishing credible air quality guidelines to protect biodiversity, and the implications of global changes in air pollution concentrations for biodiversity.

Sources and Environmental Pathways of Air Pollutants

Historical Overview

The impact of air pollutants derived from human activity on vegetation and animals has been recognized for many centuries. The English diarist John Evelyn wrote a pamphlet on air pollution in London, published in 1661, in which he noted, "It is the horrid smoke which kills our Bees and Flowers abroad, suffering nothing in our gardens to bud, display themselves or ripe." There is also evidence from historical records of changes in biodiversity as a result of pollution. For example, until the early 1800s the dominant vegetation of the upland bogs of the Peak District in the southern Pennines of England was *Sphagnum* moss species. However, with the onset of the industrial revolution in the surrounding valleys, air pollutant levels in the region increased rapidly. The *Sphagnum* species began to disappear, to be replaced by vegetation dominated by cotton grass (*Eriophorum vaginatum*).

Overall, there has been a reduction in species diversity, as species associated with the ombrotrophic *Sphagnum* species, such as sundews (*Drosera* species) and marsh andromeda (*Andromeda polifolia*), have also been lost. There is little doubt in this case that the change in community composition was a result of the direct elimination of the sensitive *Sphagnum* species by increased sulfur deposition.

During the past century, the range and quantities of chemicals discharged into the atmosphere from industry, transport, agriculture, energy production, domestic heating, and many other human activities, have increased dramatically. Once discharged into the atmosphere, these compounds are physically dispersed in the atmosphere and may undergo chemical transformations that alter their potential environmental impact. The environmental impact of air pollutants will depend on their concentration in the environment, or on the dose received or accumulated by the target organism.

Sources, Distribution, and Effects of Major Air Pollutants

Air pollutant problems vary greatly in their spatial scales. Some are very local in character, with the environmental impact of the pollution restricted to the immediate vicinity of, for example, a road or a factory. Other problems are regional in character as a result of the long-range transport of pollutants such as acid deposition and tropospheric ozone. Similarly, pollutant impacts may vary on different temporal scales. Some impacts, for example, are the result of an accidental release of large pollutant concentrations, which may cause an immediate impact on biodiversity, and from which there may be a slow and gradual recovery, whereas others are the result of an accumulation of pollutant deposition over years or even decades.

This article provides an overview of the ways in which pollutants can affect ecological processes and biodiversity.

Table 1 Summary of major sources and impacts of air pollutants of relevance to biodiversity

<i>Pollutant</i>	<i>Major sources</i>	<i>Major impacts</i>	<i>Scale of effects</i>
Sulfur dioxide (SO ₂)	Power generation: industry, domestic, and commercial heating	Forest decline; elimination of lichens and bryophytes	Local
Nitrogen oxides (NO _x) and ammonia (NH ₃)	Power generation and transport (NO _x); intensive agriculture (NH ₃)	Altered plant growth and enhanced stress sensitivity; soil acidification and eutrophication	Local, regional
Acid deposition	Secondary pollutant formed from SO ₂ and NO _x	Soil and freshwater acidification: forest decline	Regional
Ozone (O ₃)	Secondary pollutant formed from hydrocarbons and NO _x	Reduced plant growth: forest decline	Regional
Toxic metals (e.g., lead and cadmium)	Smelting industry; transport (lead)	Reduced soil microbial activity; reduced soil invertebrate populations	Local, regional
Persistent organic pollutants (POPs)	Industry; fuel combustion; pesticide use	Bioaccumulation in food chain	Local, global

Inevitably, it is not possible to provide a comprehensive account of the effects of the vast range of contaminants emitted into the atmosphere by human activity; therefore, this article will concentrate on those air pollutants for which the greatest evidence exists of impacts on biodiversity. **Table 1** summarizes the major sources of these pollutants, their major ecological impacts, and the spatial scale of these impacts.

Deposition and Environmental Pathways

The pathways by which pollutants enter ecosystems may have direct relevance to the nature of their impacts. When pollutants enter as gases, they may be taken up directly into foliage, through stomata, or directly inhaled by animals. However, in other cases pollutants may enter ecosystems in rainfall, in cloud or mist, or as particles.

The pathways of aurally deposited pollutants through ecosystems, and the mechanisms by which they affect biodiversity, are varied. There are three major groups of air pollutants considered in this article which are of significant concern in terms of biodiversity and which differ generically in the nature of their pathways from the atmosphere to the site of biological impact.

1. Acidifying and eutrophifying pollutants, such as sulfur dioxide, nitrogen oxides, and ammonia, which are also deposited as sulfate, nitrate, and ammonium in wet deposition. These gases may have direct effects on organisms, but over longer periods they can also lead to acidification and eutrophication of soils and freshwaters, with implications for biodiversity.
2. Photochemical oxidants, primarily ozone, which are not emitted directly into the atmosphere but are secondary pollutants formed as a result of reactions involving nitrogen oxides and volatile organic compounds, which require sunlight and high temperatures. Hence photochemical oxidants are characteristic of warm climates. The main impacts of ozone on biodiversity are through direct uptake into, and effects on, leaf tissue.

3. Metals are deposited primarily in rainfall or in particulate matter, but atmospheric deposition is only one source of these chemicals; they can also result from soil contamination or from discharges into the marine or freshwater systems. The impacts of metals result primarily from their accumulation in soils at concentrations which are toxic to soil organisms or plant roots, or through leaching into freshwaters.

There are a much wider range of specific pollutants which are not considered in this article but which may have impacts around specific industrial sources – for example, hydrogen fluoride and hydrogen chloride. Another group of chemicals, persistent organic pollutants (POPs), are of concern because of the potential for significant bioaccumulation in the food chain. There is evidence that the atmosphere can act as a pathway to redistribute these compounds through “global distillation,” in which compounds volatilize at ambient temperatures in warmer parts of the planet and are then redeposited at cooler latitudes. Thus, it is the bioaccumulation of these compounds in the polar regions which is of greatest concern; for example, Antarctic fish remote from any immediate pollution sources have been reported to contain concentrations of certain POPs which are as high as those in North Sea fish.

Mechanisms of Impacts on Biodiversity

Long-Term and Short-Term Effects on Individual Organisms

Before considering the impacts of air pollution on biodiversity at a community level, it is essential to assess the ways in which individual organisms respond to air pollutants. The impact of a pollutant on any individual organism is complex and may involve many factors. The most important of these factors is the dose of the pollutant received. This will depend on the concentration of the pollutant in the atmosphere, or other relevant medium, and the duration of exposure to it. Short-term effects of air pollution exposure at high concentrations result in acute toxicity which is usually characterized by direct

damage to exposed tissue and visible leaf injury on vegetation. In contrast, long-term effects of air pollution exposure, which may result from much lower concentrations, result in chronic toxicity, which is usually characterized by alterations in physiology, growth, and reproduction. In general, the relationship between pollutant concentration, or dose, and the response of an organism is classified as follows.

1. When the pollutant is present in sufficiently high concentrations, the organism may be killed outright.
2. At lower concentrations, the organism is able to survive, but its performance is adversely affected. For example, rates of growth or reproduction may be reduced, or changes may occur in the patterns of development or in resource allocation.
3. At even lower concentrations, the physiology and growth of the organism may be unaffected under optimal environmental conditions, but the pollutant may cause subtle morphological, physiological, or behavioral changes which lead to an altered tolerance of other environmental stresses.
4. Finally, in the case of certain pollutants, there may be positive effects at low concentrations. For example, sulfur dioxide can stimulate plant growth at low concentrations, especially in soils which are sulfur deficient, whereas nitrogen (N) deposition can also increase the growth rate of many fast-growing competitive plant species

This range of different biological responses, depending on the severity of the air pollution stress, means that different types of mechanisms exist for impacts on biodiversity. Thus, for 1, direct elimination of species may lead directly to a reduction in biodiversity. For 2, reductions in growth rates may affect the longer term viability of populations and lead to local extinctions; however a more likely outcome is a shift in competitive balance between species, which may lead to a changed community composition. In the case of 3, the pollutant has no direct effect on biodiversity but may exacerbate, or mitigate, the impacts of other stress factors. Finally, for 4, although the effect of the air pollutant on a species may be positive, increases in growth of one species may alter the competitive balance and lead to reduced populations or local extinctions of other species. Air pollution may also have effects on some species indirectly through its detrimental impacts on other components of the ecosystem. For example, elimination of forest cover through direct effects of air pollution will cause large changes in the microclimate of the forest floor, with consequences for ground vegetation and soil biodiversity. Several of these mechanisms may operate simultaneously, as explained for the case of N deposition in the section Effects of Nitrogen Deposition on Plant Species Richness and Diversity.

There is a large degree of variation between species in their sensitivity to particular pollutants; there is also often substantial genetic variation in response within species. This variation broadly relates to the ability of the organism to restrict pollutant uptake or, once it has been taken up, to detoxify, metabolize, or sequester the pollutant. Within the same genotype, other factors such as age and growth stage may also influence sensitivity to air pollutants. Finally, the dynamics of these responses are important, with pollutant

exposure frequently inducing adaptive biochemical, physiological, or morphological responses which lead to a reduction in its adverse effects.

Interactions between Air Pollutants and Other Environmental Factors

The effect of a given exposure to an air pollutant may also depend on other environmental conditions which can modify responses to the pollutant. First, they may modify pollutant dose; for example, soil water stress may lead to stomatal closure and thus to a reduced uptake of air pollutants by plants and hence reduced pollutant damage. Second, environmental factors may reduce the capacity of an organism to detoxify and assimilate pollutants; for example, it is well established, from both controlled experiments and field observations, that sulfur dioxide is more phytotoxic when plants are growing at low temperatures or under low light conditions. Third, exposure to pollutants may lead to changes in the morphology or physiology of the organism which make it more sensitive to environmental stresses; for example, increased deposition of N has been shown to increase the likelihood of defoliating pest outbreaks in heathland ecosystems.

Air pollutants rarely occur alone, and the responses to pollutant mixtures may be very different from those to the individual constituent pollutants. These interactions can operate in several different ways. First, two pollutants taken up together may have a greater effect than would be expected from knowledge of the effects of each pollutant – a so-called synergistic response. For example, uptake of sulfur dioxide and nitrogen dioxide together often has synergistic effects on vegetation. Although synergistic interactions between air pollutants have received considerable attention, there are many instances in which the effect of a pollutant mixture is not different from that of the individual pollutants or indeed there is a reduced effect – an antagonistic interaction. Second, over the longer term, the deposition of one pollutant can affect the uptake and impacts of another contaminant; for example, there is evidence that freshwater acidification resulting from deposition of sulfate and nitrate can cause increased bioaccumulation of metals such as lead, cadmium, and mercury in fish and birds. Finally, problems such as forest decline may result from complex interactions between a whole range of air pollutants, biotic, and abiotic stresses, and management factors.

Evolutionary Responses to Air Pollution Exposure

In competitive situations, it is likely that selection pressures will act in favor of individuals that are more resistant to a particular stress factor, and there is no reason that air pollution should be an exception to this, given the established intraspecific variation in response to pollution. A well established example is the evolution of industrial melanism in moths and ladybirds. Darker forms of these species have a selective advantage because of reduced predation where trees have a darkened bark, and a reduced lichen cover, caused by high concentrations of sulfur dioxide (SO₂) and smoke.

Improvements in air quality have led to a reversal of this evolutionary trend, with a decreased proportion of darker forms in the population.

Evolution of tolerance to air pollution has also been demonstrated in vegetation. Studies of emission sources in both the USA and the UK have shown that tolerance to SO₂ in annual and perennial species increases with increasing concentrations closer to the source. There is also evidence that decreasing urban SO₂ concentrations are associated with a loss of this tolerance in grass species, suggesting that the SO₂-tolerant genotypes are at a selective disadvantage in the absence of the pollutant. Where the pollutant is more widely dispersed, it is more difficult to demonstrate the phenomenon, although it would be expected to occur. For example, temporal and spatial associations between ozone exposures and the ozone tolerance of local populations of the annual species *Plantago major* strongly suggest an evolution of tolerance.

There is little evidence of the impact of evolution of air pollution tolerance on the overall genetic variation, or fitness, of a population. Where pollution stress is high, the frequency of resistant individuals is low, and a large proportion of the population is eliminated, the effect on overall genetic variation in the population is likely to be substantial. However, with less severe pollution levels, the effects may be relatively small.

Effects on Interactions between Organisms

When an air pollutant is present at a concentration which affects the physiology, growth, or reproduction of individual organisms, it is clear that the potential exists to influence the outcome of competition between species. In the case of competition between plant species, simple experiments with air pollutants such as SO₂ and ozone (O₃) have shown, as expected, that when a pollution-sensitive and pollution-resistant species (often a clover and grass species, respectively) are grown together, the presence of the pollutant shifts the balance in favor of the latter. However, although such simple experiments clearly demonstrate that pollutants can modify the outcome of plant competition, it is doubtful whether they provide much guidance about how air pollution modifies interactions between plant species in real communities. For example, the vertical stratification of forest communities, which cannot be readily reproduced in simple competition experiments, may have a major effect on community responses. Field studies of forest stands which have been damaged by industrial pollution typically report a decline in density of the dominant overstory tree species. However, in some cases this can be accompanied by an increase in density in the shrub layer as a result of the release of competitive suppression. Competitive exclusion is recognized as a major mechanism for N deposition causing reductions in species richness and loss of rare species, as fast-growing species with a high N demand increase their growth rates in response to the additional N.

Air pollution is also known to alter the relationships between plants and insect herbivores. For example, high concentrations of nitrogen oxides are probably a major factor

in the high numbers of aphids, and other phytophagous insects, found alongside major roads. **Figure 1** illustrates some of the potential interactions between air pollution, insect pests, and host plants. At high concentrations, there may be direct effects on the insects, but at lower concentrations the effect is mediated primarily through chemical changes in the host plant. In the case of SO₂ and NO₂, the effects on amino acid composition may be particularly important, whereas increased leaf N concentrations as a result of elevated N deposition can increase their palatability to most insect herbivores. Effects on the natural enemies of insect herbivores are another possible mechanism of response. These primary interactions can, as **Figure 1** demonstrates, lead to a range of secondary interactions affecting both plant performance and populations of other species at higher trophic levels.

Air pollutants can similarly modify the interactions between plants and fungal pathogens. Many pathogens are very sensitive to pollutants such as SO₂, and the absence of certain diseases producing clear visible symptoms, such as tar spot on sycamore (*Rhytisma acerinum*), has been used as a bioindicator of elevated concentrations of SO₂. Chemical and biological changes on the leaf surface induced by pollutants may critically affect the performance of fungal pathogens and other leaf microflora. Increased levels of pathogenic fungi have been reported when N deposition rates increase, possibly as a result of the decreased levels of phenolic compounds in the leaf. Pollutant exposure can also have an adverse effect on fungal mycorrhizal associations, which are crucial to the stress tolerance (including heavy metal tolerance) and competitive ability of many plant species. This may occur because of changes in soil chemistry, for example, due to mobilization of aluminum by acid deposition or accumulation of heavy metals, or because of effects above-ground leading to reduced carbon partitioning to the roots.

Effects on Bird and Mammal Biodiversity

There is very limited evidence of effects of air pollution on bird or mammal populations. Almost certainly, any effects are not due to direct effects on these organisms but due to changes in food quality or prey species composition caused by air pollution. Although there have been suggestions that declines in certain bird species in north-west Europe are associated with effects of increased atmospheric N deposition, the supporting evidence of changes induced by air pollution across the entire food webs that support these bird populations is lacking. More direct evidence is available where aquatic food webs have been disrupted by water acidification. For example, decline of the common loon, a large fish-eating predator with iconic status in Canada, have been linked to reduced breeding success on acidified lakes because of the reduced availability of fish.

Evidence of Impacts on Biodiversity

The previous section summarized the key factors which may influence the impact of air pollution on biodiversity. In

Figure 1 Model of potential interactions between air pollution, insect herbivores, and host plants. Reproduced from Bell JNB, McNeill S, Houlden G, Brown VC, and Mansfield PJ (1993) Atmospheric change: Effect on plant pests and diseases. *Parasitology* 106: S11–S24.

this section, some examples of actual impacts of air pollution on biodiversity in the field are discussed in more detail to illustrate the types of effects which have been found. In some cases, there is evidence of both the declines in biodiversity at historic high levels of air pollution and of recovery as air pollution levels have decreased. It should be noted that the evidence proving the link between exposure to air pollution and loss of biodiversity in the field is variable in quality. Where the effects are severe and localized, spatial associations between pollutant deposition and biodiversity may be readily established and, especially when the species present before operation of a local source are known, a causal link may readily be inferred. However, where the concern is related to a regional-scale deposition of air pollutants at more moderate levels and the effects on biodiversity are more subtle, possibly involving interactions between several factors, the causal link is much more difficult to establish from field observations alone, and experimental evidence allied to an understanding of the underlying mechanisms becomes more important. The examples discussed in the following sections illustrate a range of cases, from local to regional.

Effects of Sulfur Dioxide and Metals near Large Smelters

It is clear that, when present in high enough concentrations, air pollutants can cause the complete elimination of all plant species. For example, near the large Sudbury smelter in Ontario in the early 1970s, areas devoid of vegetation occurred up to 8 km from the source, and species numbers and productivity were reduced up to 20–30 km from the smelter. **Figure 2** illustrates the relationships between the stem basal area, species number, and the diversity index of overstory vegetation, and the distance from the smelter; similar relationships were found for ground vegetation, although the trend with distance was not as strong, and for insect communities. These effects were primarily attributed to the combined effects of SO_2 and metal emissions from the smelter. There was also evidence of acidification and metal accumulation in lakes near the smelter, with adverse effects on species numbers for plankton, macrophytes, and fish.

It is interesting to compare these results with the effects of large point sources of metals, which, unlike Sudbury, have

Figure 2 Forest overstory characteristics, expressed as (a) total stem basal area, (b) per unit ground area, (c) number of species, and (d) Shannon–Weaver diversity index, with distance south of the Sudbury smelter complex. minimal SO₂ emissions. One of most intensively studied areas is near the brass works at Gusum, Sweden, where the metals have accumulated in the surrounding soil over a period of three centuries. **Figure 3** shows the relationship between soil copper concentrations, which increase with proximity to the smelter, and the numbers of taxa of different groups of organisms. Lead and zinc are associated with copper, and may be contributing to these effects on biodiversity. Vascular plant species are relatively unaffected in terms of numbers of taxa, although cover and growth are reduced near the smelter; in contrast, the number of taxa of mosses, earthworms, ground lichens, and macrofungi are all significantly reduced at higher metal concentration.

The local impact of smelters also depends on soil and climate. For example, the impact of two large nickel smelters in the Kola peninsula, which produce large emissions of metals and SO₂, may be exacerbated by their location in the Arctic, where nutrient turnover rates are low and the low temperatures are likely to increase the sensitivity of vegetation to SO₂.

How fast can biodiversity recover once such large point sources of air pollution are closed? Evidence suggests that chemical recovery of soils from acidification, and the accumulation of metals, may take several decades or more. Rates of chemical recovery vary between pollutants. For example, a series of studies in woodlands near a major metal smelter in south-west England revealed that cadmium and zinc concentrations in the surface horizons have decreased since a reduction in emissions in the mid-1970s but that concentrations of lead and copper have continued to increase in the surface layers. The biological implications of these slow rates of chemical recovery are illustrated by studies since the closure of the Sudbury smelter complex, where the gradient of

disturbance and impoverished biodiversity is still visible 30 years later up to a distance of 50 km. Active restoration of vegetation, for example, through liming, fertilization, and seeding and planting, has accelerated the recovery of vascular plant biodiversity; however, this has not necessarily led to the recovery of species richness and diversity in other groups, such as insects and nonvascular plants.

Effects of Air Pollution on Lichen Biodiversity

The impacts of air pollution, and SO₂ in particular, on lichen species provide an illustration of larger scale changes in biodiversity. The disappearance of many lichen species from European and North American cities during the nineteenth and twentieth centuries has been well documented; in the UK, between 30% and 90% of species were lost from areas in which air pollution was a dominant factor. Many of these species were highly sensitive to the direct effects of relatively low concentrations of SO₂. In contrast, other lichen species are relatively tolerant, and several different scales have been developed to map SO₂ concentrations based on the occurrence of particular groups of lichen species.

In many European and North American cities, SO₂ concentrations have decreased dramatically in recent decades, but the reinvasion of lichens in response to this decline has been patchy and variable. In London, for example, it has been found that some relatively pollution-sensitive lichens have reinvaded more quickly than species which are more tolerant. There are several possible explanations for these different rates of recovery. One factor is the speed of dispersal of vegetative propagules into areas of decreasing SO₂; certain

Figure 3 Species richness of different groups of organisms related to copper concentrations in the surface soil of forests near the Gusem brass works. Reproduced from Freedman B (1995) *Environmental Ecology*, 2nd edn. London: Academic Press, and redrawn from Tyler G (1994) *Ambio* 13: 18–24.

species (so-called “zone-skippers”) are able to disperse much more rapidly than others. Another important factor is changes in bark chemistry. Recovery of epiphytic lichen species seems to be more rapid on tree species such as ash and willow, which have a relatively high pH bark, than on species with acidic bark, such as oaks. A third factor is the importance of other air pollutants, especially ammonia and nitrogen oxides, in influencing lichen biodiversity. For example, increased levels of ammonium deposition have also been associated with an increase in the cover and distribution of nitrophytic species and a loss of more acidophytic species in The Netherlands, whereas in London, there is evidence that the number of lichen species declines once nitrogen oxide concentrations exceed a critical threshold.

Effects of Nitrogen Deposition on Plant Species Richness and Diversity

The impacts of N deposition on terrestrial ecosystem biodiversity arise through a variety of mechanisms shown in Figure 4, the relative importance of which will depend on the ecosystems under consideration. These mechanisms include

direct toxicity, eutrophication, acidification, and exacerbation of other stresses.

An example of significant changes in biodiversity which are caused by N deposition, and which involve a number of the mechanisms shown in Figure 3, is the loss in recent decades of heathlands dominated by ericaceous shrubs, such as *Calluna vulgaris*, which have been replaced by acid grassland communities dominated by *Molinia caerulea* and *Deschampsia flexuosa*. This has occurred in areas such as those in the Netherlands, where there are high rates of ammonia emission from intensive agriculture. Here, the primary mechanism is a shift in the competitive balance between *Calluna* and the grass species; experimental studies clearly demonstrate that young plants of the grass species are better able to respond to increased levels of N and thus can out-compete *Calluna*.

However, the field situation is more complex because of the effect of competition for light; once a *Calluna* canopy is established, invasion by grasses is unlikely, even when there are high levels of N availability. Increased N deposition also acts by increasing the sensitivity of *Calluna* to biotic and abiotic stress factors, which will lead to canopy breakdown, and hence an opportunity for grass invasion. In particular, outbreaks of heather beetle infestations, which are favored by higher leaf

Figure 4 Summary of the main mechanisms for effects of increased nitrogen deposition on terrestrial ecosystems. The arrows inside the boxes indicate the direction of any effect, whereas feedbacks are indicated as positive (+) or negative (-). Black thin arrows indicate short-term effects, whereas gray thick arrows indicate long-term effects. Published from Bobbink and Lamers (2002).

N concentrations, can cause widespread defoliation of the *Calluna* canopy. Finally, it is likely that management practices are also significant; there have been reduced rates of grazing and sod-cutting in recent years, and these traditional management practices have been important in maintaining the low nutrient status of the heathland communities. Thus, in this case, changes in species composition may have resulted from a complex mixture of factors, including pollutant deposition, management practices, competition for light and nutrients, and the effects of climatic stress and insect herbivores.

A synthesis of the available evidence across Europe has identified a range of effects of elevated N deposition on terrestrial biodiversity including, *inter alia*: reduced species richness in acid grasslands; loss of characteristic of bryophyte species and carnivorous species, such as sundews, from peatlands; reduced species diversity and invasion of grasses in coastal dunes; and loss of epiphytic lichen species in forests. Close to large agricultural point sources, much of the N deposition is in the form of ammonia. There is a strong body of evidence of adverse effects, especially on lichen and bryophyte species, close to these point sources of ammonia. Nitrophytic species, which are sensitive to direct effects of high ammonia concentrations, decline, as do acidophytic epiphyte species, because ammonia, as a basic gas, increases tree bark pH. On a regional scale, focused field surveys have shown a close relationship between elevated N deposition and some components of biodiversity. For example, a survey of an acid grassland community in the UK showed a reduction in species richness as N deposition increased (Figure 5). In particular,

Figure 5 Species richness in 2 m × 2 m quadrats in acid grassland communities across the UK expressed as a function of nitrogen deposition. Reproduced from Stevens CJ (2004) Impact of nitrogen deposition on the species richness of grasslands. *Science* 303: 1876–1879.

forb species richness was reduced by about 75% across this gradient of N deposition. Detailed analysis of the survey results suggests that acidification was a stronger driver of the observed effects than eutrophication in these poorly buffered soils.

A number of recent studies in Europe have also analyzed data from historic and more recent large-scale ecological surveys. These studies have consistently shown either (1) a decline in species richness and, more specifically, a decline in species associated with nutrient-poor habitats or (2) little

change or even an increase in species richness, but a decline in species adapted to a low nutrient availability, including species of high conservation importance. Taken together, there is now a large body of experimental and field evidence to suggest that N deposition has had a significant adverse effect on biodiversity in many habitats of conservation importance in western and central Europe, and there is increasing evidence of such effects in North America.

As for effects of acidification and metal accumulation around smelters, the timescale for ecosystem recovery from long-term impacts of N deposition may be substantial. Most, but not all, experimental studies suggest that recovery of species number and diversity may take a minimum of 1–2 decades and, where the original cumulative deposition of N was large, recovery may take significantly longer. For example, in areas of the Netherlands where ammonium deposition has decreased greatly in the last 20–30 years, soil conditions still prevent the establishment of sensitive heathland and grassland species of high conservation value, and recovery of these species is likely to require active restoration of the necessary soil chemical conditions through nutrient removal and liming.

Effects of Ozone on Species Composition and Diversity

In the case of ozone, current trends in Europe and North America suggest that peak concentrations during photochemical episodes have declined over the past 20–30 years in response to national and regional measures to control emissions. However, at the same, northern hemispheric annual mean concentrations have increased significantly, primarily driven by global increases in emissions of precursors, and are projected to increase further over the current century. The implications of these changes in ozone exposure patterns for biodiversity are quite uncertain.

In the past, there was strong evidence from field observations linking cause and effect when ozone occurred in very high concentrations. For example, the area where the impacts of ozone on forests have been most intensively studied is in the San Bernadino mountains, which surround the city of Los Angeles. Effects of ozone began to be observed on the forest community in the 1960s. The most dominant species of these mixed-conifer forests prior to European settlement were ponderosa pine (*Pinus ponderosa*) and Jeffrey pine (*Pinus jeffreyi*) because of their tolerance of the frequent wildfires; however, these also proved to be the most sensitive species to ozone. In many areas, both species showed severe visible injury and reduced needle longevity. These were associated with reduced radial growth or even years with missing growth rings. Trees affected by ozone were more susceptible to attack by bark beetles, which was often the direct cause of mortality. Outbreaks of bark beetles were associated with drought years and high ozone concentrations. Regeneration in these forests was greater for tree species such as white fir or cedar species, which are more resistant to ozone. The patterns of change in community composition are confounded by the role of fire since current fire exclusion policies favor replacement of ponderosa pine and Jeffrey pine by more fire-sensitive species which also happen to be more ozone tolerant. Similar effects

of long-term exposure to high concentrations of ozone have been reported in other forest ecosystems, such as the declines in fir vitality which have been reported in the mountains near Mexico City.

Recent experimental studies in chamber systems have shown significant effects of small increases in mean background ozone concentration on a range of grassland species. This suggests that the increases in background ozone concentrations that are currently occurring across the northern hemisphere have the potential to have large-scale adverse effects on biodiversity. However, experimental studies are typically for periods of 1–2 years, and very few experimental studies have examined the long-term effects of ozone under field conditions. Furthermore, those species identified as ozone-sensitive based on field surveys of visible symptoms are not necessarily those on which ozone has the greatest impacts on cover or biomass. For example, an experimental study of an early successional forest community showed that ozone decreased species richness, diversity, and evenness; however, the species which dominated the community in the highest ozone treatment was blackberry, which is considered to be highly ozone sensitive on the basis of visible injury responses.

There is an increasing recognition that long-term effects of ozone on biodiversity have to be considered as just one element of wider scale environmental change. Even in the San Bernadino mountains, where ozone concentrations were historically very high, analysis of changes in species composition over more than a 25-year period suggests that a number of factors are important, including management, N deposition, and water stress as well as ozone exposure.

Effects of, and Recovery from, Water Acidification

The previous sections have focused on terrestrial, rather than aquatic, biodiversity. However, one of the most substantial large-scale impacts of air pollution over recent decades has been the effects of surface water acidification, primarily due to deposition of sulfate, in sensitive regions of northern and western Europe and north-eastern North America. This water acidification has been associated with effects on a range of groups, including invertebrates, fish (especially salmonids), algae, macrophytes, and piscivorous birds as well as impacts on a range of other ecosystem services. These effects occurred once the limited buffering potential of base cations in catchment soils were exhausted, resulting in increased concentrations of hydrogen and aluminum ions that were toxic to a range of aquatic fauna, and reduced pH and alkalinity that affected a range of aquatic plants. Loss of acid-sensitive species then had wider effects on aquatic food webs.

Since the 1980s, there have been substantial reductions in sulfur emissions across these regions, although the size and timing of these reductions varies. The evidence of biological recovery is limited and variable, but illustrates the complexity of recovery in biodiversity once ecosystems have been significantly affected by the air pollution. In Canada, for example, the evidence of chemical and biological recovery is very limited, except in regions, such as that around Sudbury (see Effects of Sulfur Dioxide and Metals near Large Smelters),

where there have been dramatic reductions in sulfur deposition. In the UK, in contrast, evidence of recovery of invertebrate and fish populations is widespread following a process of chemical recovery; however, biological recovery is far from complete and the invertebrate assemblages that are developing are not identical to those found in similar streams that have not been affected by acidification. Indeed, pre-acidification species assemblages may never be completely replaced.

A number of factors have been identified that affect both the degree of chemical recovery and the nature of biological recovery. First, the degree of emission reduction needs to be sufficient to reverse acidification. Second, there is a potential for nitrate leaching to increase in regions with high rates of N deposition, reversing or delaying the recovery from acidification. Third, management is important; active restoration, for example through liming, has clearly accelerated chemical recovery in many locations, but areas with extensive planting of conifers, for instance in the UK, have tended to show greater degrees of acidification, and slower rates of chemical recovery, than those with no afforestation.

In the UK, dispersal is not a significant barrier to reestablishment of acid-sensitive invertebrate species, since adults arrive but fail to establish viable populations. One important factor restricting species re-establishment, even when mean pH has reached appropriate values is the effect of acid episodes. Such episodes, which may be linked, for example, to droughts or to sea-salt events, can lead to short periods when hydrogen and aluminum concentrations are still toxic to acid-sensitive groups such as mayflies. A trend to warmer wetter winters is also a factor, as this also increases the frequency of acid episodes. Such factors may explain why, although some acid-sensitive invertebrate species have reappeared, these are only a small proportion of the acid-sensitive species that were originally identified. Competition for ecological niches from acid-tolerant populations that have now become established may be another significant factor.

Air Quality Guidelines to Protect Biodiversity

The long-range transport of air pollutants, and their regional-scale impacts, means that local measures to protect biodiversity in specific areas, such as national parks or nature reserves, may have little value. For example, many of the national parks in the USA are affected by ozone pollution, and many sites of high conservation value in upland areas of the UK have been affected by acidification. It is therefore clear that the prevention of adverse effects on biodiversity requires measures to reduce emissions and to manage air quality in the regions of concern.

However, complete control of atmospheric emissions is impossible, and the costs of decreasing air pollution emissions typically increase greatly as the degree of removal increases. Thus, it is important to assess how far pollutant emissions should be reduced in order to ensure an acceptable degree of protection for biodiversity. In Europe, the concept of a critical load has been used to assess the need for further measures to protect biodiversity; a critical load is defined as "a quantitative estimate of an exposure to one or more pollutants below

which significant harmful effects on specified sensitive elements of the environment do not occur according to present knowledge." The critical load refers to the pollutant input in all forms of deposition; critical levels, defined in terms of atmospheric concentrations over a given averaging time, have also been defined for pollutant gases. The critical load concept is based on a precautionary approach and relates to the long-term cumulative effects of deposition on ecosystem function and biodiversity. Thus, wherever current deposition rates exceed critical loads, but field studies demonstrate no adverse effects on biodiversity, action to reduce emission rates may still be justified to prevent future damage. Dynamic modeling can be a useful complement to the application of critical load values, by indicating the timescale over which changes in air pollutant emissions will lead to a change in soil or water chemistry that would be critical for particular groups of species.

Although the critical load concept has been valuable in providing an effects-based approach to international negotiations on trans-boundary air pollution in Europe, it is important to appreciate the difficulties of defining thresholds, in terms of pollutant deposition or concentration, for adverse effects on biodiversity. These difficulties arise from two major sources.

1. There are conceptual problems in defining what is meant by a significant harmful effect, both scientifically and in terms of societal judgment. For example, are small shifts in species composition of urban lichen communities, or changes in species composition of the invertebrate fauna of a woodland floor which do not affect nutrient cycling, actually significant harmful effects? This issue often needs to be addressed in areas where other human impacts, such as changes in land use, have already changed substantially the structure and composition of plant and animal communities.
2. Although the adverse effects of air pollution on biodiversity may be clear in situations in which they are present in high concentrations, as a threshold concentration is approached the effects become gradually more subtle and are difficult to detect under field conditions. Although experimental dose-response relationships may be able to define thresholds for short-term effects on single organisms under controlled conditions, the long-term cumulative effects of air pollution on complex communities cannot be reliably assessed using current experimental approaches.

Implications of Global Changes in Air Pollution for Biodiversity

In the past few decades, measures have been taken in Europe and North America which have reduced atmospheric emissions of many pollutants. Although recovery of biodiversity in ecosystems affected by these pollutants may take time, and may not result in the same community as that originally present in a particular location, major new impacts on biodiversity due to increases in atmospheric emissions are unlikely in these regions. In contrast, the past two decades have

Figure 6 Distribution of nitrogen deposition in the G200 ecoregions of the world. Reproduced from Bobbink R, *et al.* (2010) *Ecological Applications* 20: 30–59, using modeled nitrogen deposition from Dentener, *et al.* (2006) and G200 data from Olson and Dinerstein (2002).

seen large increases in atmospheric emissions in parts of Asia, Africa, and Latin America.

To illustrate the threat to biodiversity from these global changes in patterns of air pollution emissions, **Figure 6** shows modeled rates of N deposition in 2000 in the G200 ecoregions, that is, global priority conservation areas that contain distinct and unique assemblages of natural communities and species. It is clear that high rates of N deposition were not only found in Europe and North America, but also in China and parts of south- and south-east Asia. In all these regions, critical loads that have been recommended to protect sensitive ecosystems in Europe and North America were exceeded in 2010. The consequences of excess N deposition for biodiversity were described in the section Effects of Nitrogen Deposition on Plant Species Richness and Diversity in general terms, but their specific impacts in sensitive ecosystems in east, south-east, and south Asia are unknown.

Model projections suggest that N deposition will increase not only in these rapidly developing regions of Asia, but also in many parts of Africa and Latin America, by 2030, although the validity of any projections depends critically on economic growth rates and the extent to which pollutant emissions are controlled. What is certain is that the authors lack experimental and field data to assess the consequences for local biodiversity of these increases in N deposition, as well as in sulfur deposition, ozone concentrations, and exposure to other pollutants. These large gaps in knowledge are critical for any assessment of the consequences of both current and future air pollution emissions for global biodiversity.

Concluding Remarks

This article has summarized some key aspects of air pollutant impacts on biodiversity. Although the text has, for the sake of clarity, focused on a limited range of pollutants, many of the same principles apply in the case of other air pollutants and

other ecological impacts. Although in the past, very high concentrations of air pollutants were the dominant factor causing local changes in biodiversity, most of the situations of concern today in Europe and North America tend to involve more widely dispersed pollutants at lower concentrations, the effects of which may only become apparent over many years or even decades. In such cases, air pollution is no longer the single dominant factor but one of a range of biological, climatic, and soil factors which may influence biodiversity. If we want to fully understand the role of air pollution in such situations, it is essential that we gain further understanding of the ways in which pollution can interact with these other factors and base our analysis of pollutant impacts more clearly within an ecological framework. It is also vital that we acquire more knowledge in the many areas of the planet where recent and future increases in air pollutant exposure are a significant potential threat to the characteristic species and ecosystems.

Glossary

Atmospheric lifetime Timescale characterizing the rate of removal of a gas from the atmosphere, generally defined as the time to remove 63.2%, the e-folding time.

Greenhouse gases Gases like water vapor and carbon dioxide that can affect climate through their absorption and re-emission of terrestrially emitted infrared radiation.

Mixing ratio Ratio of the concentration of a gas to the concentration of air. It can be defined in terms of volume (e.g., molecules per m³) or mass (e.g., g m⁻³).

Oxidizing capacity Self-cleansing ability of the atmosphere through oxidative reactions.

Ozone Molecule composed of three oxygen atoms that is extremely important to life on Earth because of its absorption of solar ultraviolet radiation; ozone is also a greenhouse gas.

Photochemical source or sink Production or loss of an atmospheric gas involving photodissociation or chemical reactions.

Photodissociation Destruction of a molecule through absorption of solar radiation and subsequent breaking of one or more chemical bonds.

Introduction

As seen in **Table 1**, the bulk of the Earth's dry atmosphere is composed of molecular nitrogen (N₂, 78.08%), molecular oxygen (O₂, 20.95%), and argon (Ar, 0.93%). While the remaining gases comprise only about 0.03% of the Earth's atmosphere, many of them are extremely important to the climate and habitability of our planet. These gases are the primary focus of this article. The concentrations of many of these gases are also being affected by human activities.

Some of the gases listed in **Table 1**, like ozone (O₃), affect the transmission of solar radiation in the atmosphere. Others, like carbon dioxide (CO₂), affect the absorption of terrestrially produced infrared radiation and are called greenhouse gases. These types of gases are therefore linked to the physical climate system of the Earth. Increasing concentrations of greenhouse gases have resulted in concerns about changes in climate, or global warming as it is often referred to in the public media. Some trace gases, such as sulfur dioxide (SO₂) and hydrogen sulfide (H₂S), can affect climate through their role as precursors in the production of atmospheric particles. The resulting sulfate particles can scatter solar radiation, thus preventing some of it from reaching the Earth's surface. These particles can also serve as condensation nuclei in the formation of clouds.

The ozone layer is a term that refers to the distribution of ozone that is naturally formed in the stratosphere. This layer protects life on Earth from harmful levels of solar ultraviolet radiation (UV-B). Chlorofluorocarbons (CFCs) and other chlorinated and brominated halocarbons are emitted by a variety of human activities. Atmospheric measurements have clearly corroborated theoretical studies showing that the chlorine and bromine released from the destruction of these halocarbons in the stratosphere have been reacting to destroy significant amounts of ozone over the last few decades.

Gases like hydroxyl (OH), ozone, and hydrogen peroxide (H₂O₂) control the oxidizing capacity of the atmosphere, and destroy many pollutants emitted into the atmosphere through

chemical reactions. Hydroxyl has been referred to as the "atmospheric vacuum cleaner." It is generated primarily by the interactions of water vapor, ozone, and UV-B, and is destroyed primarily through reaction with carbon monoxide (CO) and methane (CH₄).

Emissions of trace gases in urban regions can result in atmospheric pollution referred to as photochemical smog. For example, ozone, a potential cause of health problems in polluted regions, can be formed in the air by chemical reactions following emissions of nitrogen oxides (NO_x) and volatile organic gases (VOCs), including hydrocarbons. NO_x is the sum of the concentrations of nitric oxide (NO) and nitrogen dioxide (NO₂), while NO_y also includes other reactive nitrogen gases like nitric acid (HNO₃).

Missing from **Table 1** is water vapor, a gas with highly variable concentration, whose amount in the atmosphere is dependent on evaporation and hydrological cycle processes associated with weather. The concentration of atmospheric water vapor can be affected at the local scale by human activities but is not thought to be directly affected at the global scale by human activities. However, climate change can affect the amount of water vapor; the atmosphere can hold more water vapor under a warmer climate. Water vapor is also the most important of the greenhouse gases; its changes in concentration are generally considered in climate studies as being part of the climate response to other forcings, either natural or human-driven.

Biodiversity affects the concentrations of atmospheric trace gases and can also be affected by changing concentrations of atmospheric gases. The biosphere is an important component in the biogeochemical cycles of carbon, nitrogen, and sulfur. As a result, the sources and sinks of many atmospheric gases are strongly affected by changes in the biosphere. For example, deforestation is contributing to the increase in concentration of carbon dioxide. Also, biospheric growth from increasing amounts of atmospheric carbon dioxide can increase the rate of removal of CO₂ from the atmosphere. Local air pollution, changes in climate, and changes in stratospheric ozone can

Table 1 Typical concentrations and primary sources of some of the important gases in the atmosphere (based on WMO, 2010, and Blasing, 2010; wherever possible, values correspond to the globally averaged concentration in 2009)

<i>Constituent</i>	<i>Chemical formula</i>	<i>Volume mixing ratio (dry air)^a</i>	<i>Major sources and remarks</i>
Nitrogen	N ₂	78.084%	Biological
Oxygen	O ₂	20.948%	Biological
Argon	Ar	0.934%	Inert
Carbon dioxide	CO ₂	386 ppm	Combustion, ocean, biosphere
Methane	CH ₄	1.8 ppm	Biogenic, human-related
Hydrogen	H ₂	0.55 ppm	Biogenic, human-related, photochemical
Nitrous oxide	N ₂ O	0.32 ppm	Biogenic, human-related
Carbon monoxide	CO	0.05–0.2 ppm	Photochemical, human-related
Ozone (troposphere)	O ₃	0.01–0.5 ppm	Photochemical
Ozone (stratosphere)	O ₃	0.5–10 ppm	Photochemical
Nonmethane hydrocarbons	C ₂ H ₂ , etc.	5–20 ppb	Biogenic, human-related
CFC-11	CFCl ₃	240 ppt	Human-related
CFC-12	CF ₂ Cl ₂	536 ppt	Human-related
CFC-113	CCl ₂ FCFCl ₂	76 ppt	Human-related
Halon-1211	CBrClF ₂	4.3 ppt	Human-related
Halon-1301	CBrF ₃	3.3 ppt	Human-related
Methyl bromide	CH ₃ Br	10 ppt	Ocean, human-related
Methyl chloride	CH ₃ Cl	550 ppt	Ocean, biogenic, human-related
Nitrogen species	NO _y	10 pptv–1 ppm	Soils, lightning, human-related
Ammonia	NH ₃	10 pptv–1 ppb	Biogenic
Hydroxyl	OH	0.1 pptv–10 ppt	Photochemical
Peroxy	HO ₂	0.1 pptv–10 ppt	Photochemical
Hydrogen peroxide	H ₂ O ₂	0.1–10 ppb	Photochemical
Formaldehyde	CH ₂ O	0.1–1 ppb	Photochemical
Sulfur dioxide	SO ₂	10 pptv–1 ppb	Photochemical, volcanic, human-related
Di-methyl sulfide	CH ₃ SCH ₃	10–100 ppt	Biogenic
Carbon disulfide	CS ₂	1–300 ppt	Biogenic, human-related
Carbonyl sulfide	OCS	500 ppt	Biogenic, volcanic, human-related
Hydrogen sulfide	H ₂ S	5–500 ppt	Biogenic, volcanic

^appm = parts per million by volume = number of molecules in 10⁶ molecules of air; ppb = parts per billion by volume = number of molecules in 10⁹ molecules of air; ppt = parts per trillion by volume = number of molecules in 10¹² molecules of air.

affect the biosphere and have an impact on biodiversity. For example, acid rain or acidification resulting from emissions of nitrogen- and sulfur-containing gases can affect landscapes in many ways.

The Changing Composition

Without human intervention, concentrations of many atmospheric gases would be expected to change slowly. Ice core measurements of the gases trapped in ancient ice bubbles indicate that this was the case before the last century. We also know that major natural events, like a volcanic eruption, can enhance concentrations of some gases, such as sulfur dioxide, for as long as a few years. However, since the beginning of the Industrial Age, emissions associated with human activities have risen rapidly. Agriculture, industry, waste disposal, deforestation, and especially fossil fuel use have been producing increasing amounts of carbon dioxide, methane, nitrous oxide (N₂O), CFCs, and other important gases. Because of these increasing emissions, atmospheric levels of these gases have been building at an unprecedented rate, resulting in effects on ozone, another radiatively important gas, and raising concerns regarding the impact of these gases on climate. Although all of

these gases are having some influence on climate, changes in the amount of atmospheric carbon dioxide is of particular interest in the major concerns about a human-induced effect on temperature, precipitation, and other aspects of our climate system. In addition, changes in the human-related emissions and atmospheric concentrations of small particles or aerosols are also influencing climate. The following discussion focuses on the changing concentrations and budgets of a number of these gases.

Carbon Dioxide

Of all the greenhouse gases, carbon dioxide has been undergoing the largest changes in concentration. It is also the gas of most concern for analyses of the potential human effects on climate. Accurate measurements of atmospheric CO₂ concentration began in 1958 at the Mauna Loa Observatory in Hawaii. **Figure 1** shows that the annually averaged concentration of CO₂ in the atmosphere has risen from 316 parts per million (ppm) in 1959 to 386 ppm in 2009. The CO₂ measurements exhibit a seasonal cycle, which is mainly caused by the seasonal uptake and release of atmospheric CO₂ by terrestrial ecosystems. The average annual rate of increase over the whole time period is about 1.2 ppm or 0.4% per year, with

Figure 1 Observed monthly average of carbon dioxide (CO₂) concentration (ppmv, parts per million by volume) from Mauna Loa, Hawaii (measurements began by CD Keeling and continue under the auspices of the US National Oceanic and Atmospheric Administration (NOAA)). Seasonal variations are primarily due to the uptake and production of CO₂ by the terrestrial biosphere.

the rate of increase over the last decade being about 1.6 ppm yr^{-1} . A significant slowing in the growth rate occurred in 1992 (when it dropped to 0.6 ppm), but by 1994 the rate had risen above the average over the decade. This anomaly in the carbon cycle system appears to be related to atmospheric aerosols resulting from the Mount Pinatubo volcanic eruption in June 1991 and the corresponding effects on solar irradiances and natural emissions/uptake of CO₂. A rate increase in 1998 was related to biospheric response to a major El Niño event.

Measurements of CO₂ concentration in air trapped in ice cores indicate that the preindustrial concentration of CO₂ was approximately 280 ppm. These data show that carbon dioxide concentrations fluctuated by $\pm 10 \text{ ppm}$ around 280 ppm for well over a 1000 years until the recent increase to the current $380 + \text{ ppm}$, an increase is greater than 30%.

Why has the atmospheric concentration of CO₂ increased so dramatically? Analyses with models of the atmosphere–ocean–biosphere system of the carbon cycle indicate that human activities are primarily responsible for the increase in CO₂. Two types of human activities are primarily responsible for emissions of CO₂: fossil fuel use, which released about 6.0 gigatons of carbon (ppb; GtC a gigaton is 10^9 tons) into the atmosphere in 1990, and land use, including deforestation and biomass burning, which may have contributed about $1.6 \pm 1.0 \text{ GtC}$ in addition to that from fossil fuels. Since 1751 approximately 337 billion tons of carbon have been released to the atmosphere from the consumption of fossil fuels and cement production. Half of these emissions have occurred since the mid-1970s. By 2007, the CO₂ contribution from fossil fuel burning was 8.3 GtC yr^{-1} (Boden *et al.*, 2010), an increase of 1.7% relative to 2006.

This added atmospheric carbon resulting from human activities is redistributed within the atmospheric, oceanic, and biospheric parts of the global carbon cycle, with the dynamics

of this redistribution determining the corresponding rise in atmospheric CO₂ concentration. About 40% of the added CO₂ from human activities remains in the atmosphere while about 60% is transferred to the oceans and terrestrial biosphere.

Analyses of the carbon budget previously implied a mismatch between observed levels of CO₂ and known loss processes. This sink has been well explained in terms of increased net carbon storage by the terrestrial biomass stimulated by the CO₂ fertilization effect (increased plant growth in an atmosphere of higher CO₂ concentration) and other biospheric processes.

Emissions from Fossil Fuel Consumption

Carbon dioxide is emitted when carbon-containing fossil fuels are oxidized by combustion. Carbon dioxide emissions depend on energy and carbon content, which ranges from 13.6 to 14.0 MtC EJ^{-1} for natural gas, 19.0–20.3 for oil, and 23.9–24.5 for coal. Other energy sources, such as hydro, nuclear, wind, and solar, have no direct carbon emissions. Biomass energy, however, is a special case. When biomass is used as a fuel, it releases carbon with a carbon-to-energy ratio similar to that of coal. However, the biomass has already absorbed an equal amount of carbon from the atmosphere prior to its emission, so that net emissions of carbon from biomass fuels are zero over its life cycle.

Human-related emissions from fossil fuel use have been estimated as far back as 1751. Before 1863, emissions did not exceed 0.1 GtC yr^{-1} . However, by 2007 they had reached 8.3 GtC yr^{-1} , giving an average emission growth rate slightly greater than 3% per year over the last two and a half centuries. Recent growth rates have been significantly lower, at 1.8% per year between 1970 and 1995. Emissions were initially dominated by coal. Since 1985, petroleum products have been the

main source of emissions despite their lower carbon content. The regional pattern of emissions has also changed. Global emissions were once dominated by Europe and North America, but now developing nations, especially China and India, are providing an increasing share of emissions. By 2007, developing countries (including China and India as part of the Annex I nations being used in international policy discussions) account for more than half of global emissions.

Emissions from Land Use Changes

The biosphere holds approximately 560 GtC in the form of aboveground biomass, and an additional 1200 GtC in soils and detritus. These pools form the principal reservoirs from which terrestrial systems can exhaust or sequester carbon. Evaluations of carbon releases from vegetation and soils based on changes in land use indicate that the global net flux during the period 1850–2000 was 148.6 Pg C, about 55% of which was from the tropics (Houghton, 2008). During the period 1990–2005, the greatest regional flux was from South and Central America (11.3 Pg C). The global total flux averaged 1.5 Pg C yr⁻¹ during the 1980s and 1.56 Pg C yr⁻¹ during the 1990s, dominated by fluxes from tropical deforestation. The global total flux averaged 1.47 Pg C yr⁻¹ during the period from 2000 to 2005.

Methane

Although methane's atmospheric abundance is less than 0.5% that of CO₂ on a molecule-by-molecule basis, a molecule of CH₄ is approximately 50 times more effective as a greenhouse gas in the current atmosphere than CO₂. When this is combined with the large increase in its atmospheric concentration, methane becomes the second most important greenhouse gas of concern to climate change. Based on analyses of ice cores, the concentration of methane has more than doubled since preindustrial times. The current globally averaged atmospheric concentration of methane is about 1.8 ppm (Figure 2). Continuous monitoring of methane trends in ambient air indicated that from 1979 to 1989, the concentration increased at an average of about 16 parts per billion (ppb by volume) or 1% per year, but has declined since then, reaching roughly zero-change in the early 2000s. Since 2006, the concentration of CH₄ has been increasing at a rate of roughly 5 ppb yr⁻¹.

There are a number of ideas to explain these rapid changes in the growth rate, ranging from suggested reductions in emissions from anthropogenic or natural sources to a slowing in the rate of CH₄ removal. However, the best indications are that the sharp increase and the subsequent dip in the early 1990s were connected to changes in atmospheric chemistry and temperature induced by the 1991 Pinatubo eruption. Yet the cause of the longer term global decline in methane growth is still not well understood, although it may be that much of the earlier rapid increase in methane emissions from agricultural sources has been slowing down. The recent increase in emissions is also not well understood.

The Methane Budget

Methane emissions come from a number of different sources, both natural and anthropogenic. One type of human-related

emissions arises from biogenic sources from agriculture and waste disposal, including enteric fermentation, animal and human wastes, rice paddies, biomass burning, and landfills. Emissions also result from fossil fuel-related methane sources such as natural gas loss, coal mining, and the petroleum industry. Methane is emitted naturally by wetlands, termites, other wild ruminants, oceans, and hydrates. Based on recent estimates, current human-related biogenic, and fossil fuel-related sources for methane are approximately 275 and 100 tetragrams, or 10¹² g) CH₄ yr⁻¹, respectively, while total natural sources are around 170 TgCH₄ yr⁻¹.

Because of the variety of methane sources, emissions are affected by numerous factors, including energy use, human population distributions, agricultural practices, and climate. These factors complicate the resolution of past emissions and make predictions of future CH₄ emissions difficult. Estimates of historical methane emissions can be obtained by analyses of past measurements of atmospheric CH₄ concentrations and by analyses of emissions from the different sources. Such studies suggest that, although methane emissions have climbed rapidly over the past four decades, the relative importance of agricultural sources may be declining, whereas the importance of nonagricultural sources related to fossil fuel use and waste disposal is on the increase.

In contrast to the numerous sources of methane, there are only one major and two minor sinks for tropospheric methane. Reaction with the hydroxyl radical is responsible for the removal of approximately 510 TgCH₄ yr⁻¹ (88% of the total sink). The remainder of the CH₄ is removed through reactions with soil (30 TgCH₄ yr⁻¹, or ~5%) or transport to the stratosphere (40 TgCH₄ yr⁻¹, or ~7%).

Nitrous Oxide

Nitrous oxide is a greenhouse gas that on a molecule-to-molecule basis is 200 times more efficient than CO₂ in absorbing infrared radiation. Also, through reactions with excited oxygen atoms, N₂O is the primary source of the nitrogen oxides that account for a significant fraction of the natural destruction of ozone in the stratosphere. Atmospheric measurements and ice core data indicate a continuous increase in N₂O from a preindustrial concentration of about 275 ppb. In 2007, the mean atmospheric concentration of N₂O was about 320 ppb, with a current growth rate of 0.2–0.3% per year.

Nitrous oxide is produced by various natural and human-related sources, most of which are not well quantified. Current estimates of mean emissions from natural sources include: oceans, 3.8 TgN yr⁻¹; and soils, 6.6 TgN yr⁻¹. Anthropogenic sources include agriculture, 2.8 TgN yr⁻¹; biomass burning, 0.7 TgN yr⁻¹; industrial sources, 0.7 TgN yr⁻¹; and river and estuaries, 1.7 TgN yr⁻¹. Large uncertainties associated with the numerous small sources that make up the N₂O budget make it difficult to fully explain its increase in concentration.

The major sink for N₂O is photodissociation by sunlight in the stratosphere. The current best estimate for stratospheric removal, based on stratospheric chemistry modeling, is 12.5 TgN yr⁻¹. There is some evidence that N₂O is consumed by certain soils, but there are not enough data to make a reasonable global estimate of this sink.

Figure 2 (Top) Globally averaged atmospheric methane (CH_4) concentrations (parts per billion (ppb) by volume) derived from the NOAA Climate Monitoring and Diagnostics Laboratory air-sampling sites by Dlugokencky EJ, Bruhwiler L, and White JWC (2009) Observational constraints on recent increases in the atmospheric CH_4 burden. *Geophysical Research Letter* 36: L18803. doi:10.1029/2009GL039780. The solid line is a de-seasonalized trend curve fitted to the data. The dashed-line is a model-estimated (that accounts for CH_4 emissions and loss in the atmosphere) calculated trend that fit to the globally average values. (Bottom) Atmospheric CH_4 instantaneous growth rate (ppb yr^{-1}), which is the derivative with respect to the trend curve shown in the bottom panel.

Chlorofluorocarbons and Other Halocarbons

Halocarbons are greenhouse gases that can contribute to climate change, and they are also largely responsible for stratospheric ozone loss over recent decades. Because of their dual impact, they are of particular concern to environmental health. Among the most potent halocarbons in the current atmosphere are the CFC's CFC-11 (CFCl_3) and CFC-12 (CF_2Cl_2). One molecule of CFC-11 or CFC-12 in the atmosphere is, respectively, 12,400 and 15,800 times more effective as a greenhouse gas than one molecule of CO_2 . With the exception of the naturally occurring portions of CH_3Cl and CH_3Br emissions, all the halocarbons in the atmosphere are man-made. Their inertness and long lifetimes have made them attractive chemicals for use as propellants, refrigerants, fire retardants, and other industrial applications. Natural sources of CH_3Cl from ocean surface waters and wood-rotting fungi may account for

as much as half of atmospheric CH_3Cl , with biomass burning (some of which is natural) being the other primary source. Roughly half of the CH_3Br comes from the oceans, while biomass burning and its use as a soil fumigant account for the majority of its remaining emissions into the atmosphere.

Halocarbons containing chlorine or bromine are of particular concern with regard to destruction of stratospheric ozone. Bromine and chlorine effectively catalyze ozone destruction cycles. These halocarbons, plus others such as the perfluorocarbons (PFCs) and the hydrofluorocarbons (HFCs) that contain fluorine instead of chlorine, also have the potential to affect climate change since these chemical species characteristically have strong infrared absorption features.

Measurements of CFCs and other compounds by the NOAA Climate Monitoring and Diagnostics Laboratory at sites throughout the world are shown in Figure 3. CFC-11 and CFC-12 have the largest atmospheric concentrations, at 0.24 and

Figure 3 Changes in measured concentrations of various important halogenated compounds over time, showing the initial rise until the last few decades and the beginning of a recent decline in several of the important compounds. Data are based on measurements from NOAA (these NOAA data courtesy of J Elkins, S Montzka, and G Dutton).

0.54 ppb, respectively. The tropospheric concentrations of both of these gases were increasing at about 4% per year in the early 1990s, but are now declining. The use of these compounds has diminished greatly, with all but a few minor essential applications being banned as a result of the international agreement of the Montreal Protocol to protect the stratospheric ozone layer. The atmospheric concentrations of CFC-113 ($\text{C}_2\text{F}_3\text{Cl}_3$) were increasing at about 10% per year in the early 1990s but has also slowed greatly, with a current concentration of about 0.08 ppbv. Abundances of the shorter-lived controlled compound methyl chloroform (CH_3CCl_3), have declined appreciably. Hydrochlorofluorocarbon (HCFC) 22 (CHF_2Cl), a refrigerant often found in home air conditioners, has gained increased use as a replacement for CFCs and its concentration had been increasing at about 5–6% per year since 1995 but has slowed down recently. The measured concentrations of several other replacements are also increasing.

All of the fully halogenated CFCs have long atmospheric lifetimes. The lifetime of CFC-11 is about 50 years, while the lifetime of CFC-12 is about 100 years. The atmospheric lifetimes of HCFCs, HFCs, and other halocarbons containing hydrogen tend to be much shorter than those of the CFCs. Because of these shorter lifetimes, less of the replacement compounds containing chlorine and bromine reach the stratosphere, and they have less effect on ozone than the CFCs.

Bromine is more effective at destroying ozone than chlorine. Therefore, early rapid increases in atmospheric concentrations of bromine-containing halons, most notably Halon-1301 (CF_3Br) and Halon-1211 (CF_2ClBr), have caused concern. Despite their control under the 1997 Montreal Protocol on Substances That Deplete the Ozone Layer, the concentrations of several halons, including H-1211 and H-1301, continue to increase. Primary destruction of these compounds occurs through photolysis, resulting in long atmospheric lifetimes (65 years for H-1301 and 20 years for H-1211).

However, these compounds currently have small atmospheric concentrations, about 4 ppt or less, and hence their contribution to the absorption of infrared radiation is considered minimal.

Other Gases

Carbon Monoxide

In addition to its potential effects on health in polluted areas, carbon monoxide affects the oxidizing capacity of the atmosphere through its reactivity. The reaction of carbon monoxide with OH is the primary sink for atmospheric OH. This reaction also yields an additional source of the greenhouse gas CO_2 .

The global emissions of CO are still poorly understood. Sources of carbon monoxide include incomplete combustion processes (complete combustion yields CO_2 rather than CO). Emissions of CO from fossil fuel combustion peak between 30° and 60° N latitude. More than 70% of the CO from the biomass burning source is emitted in tropical regions. Chemical decomposition of methane and other hydrocarbons is also an important source. It is estimated that about two-thirds of current atmospheric CO results from human activities. Total sources are about 1100 TgC yr^{-1} with a large uncertainty range. As a result of its short lifetime (2–3 months) and the high spatial variability of its sources, the atmospheric concentration of CO varies greatly in time and space. Annually averaged concentrations of CO peak at about 0.2 ppm at high northern latitudes; minimum concentrations of about 0.06 ppm occur throughout most of the Southern Hemisphere. Long-term trends up to 1990 suggest that CO concentrations had been increasing in the Northern Hemisphere at about 1% per year, with little evidence of an increase in the Southern Hemisphere. After 1990, concentrations show little change.

Nonmethane Hydrocarbons

Nonmethane hydrocarbons (NMHCs) in the presence of nitrogen oxides (NO_x) contribute to the formation of tropospheric ozone and stratospheric H_2 . They can also react with nitrogen species to produce the atmospheric gas peroxyacetyl nitrate (PAN), which is a long-lived reservoir of reactive nitrogen. Oxidation of NMHCs is an additional source of CO and ultimately CO_2 .

There are many anthropogenic and natural sources emitting NMHCs into the atmosphere. Anthropogenic sources result from all aspects of human activity, including chemical manufacturing, vehicle exhaust, food processing, refuse disposal, biomass burning, and energy production. Global emissions from anthropogenic activities are estimated at roughly 140 Tg yr^{-1} . Emissions from the natural sources are less well known.

Nitrogen Oxides

Emissions of nitrogen oxides have been a cause of concern because of their role as primary pollutants in photochemical smog and their contribution to acid wet and dry deposition. Nitrogen oxides are also important because of their indirect effect on climate through their role in affecting global ozone

concentrations. Although NO_x species are relatively short-lived, they can react chemically with hydrocarbons to produce PAN. The constituent PAN provides a reservoir for nitrogen oxides that can be transported long distances to affect ozone chemistry well downstream from the sources. The lifetime of PAN depends strongly on temperature.

There is significant uncertainty in the sources of nitrogen oxides, with the total source being estimated to be roughly $42\text{--}47 \text{ TgN yr}^{-1}$. The largest sources of reactive nitrogen in the troposphere are fossil fuel combustion, biomass burning, lightning discharges, microbial activity in soils, aircraft emissions, and transport from the stratosphere. Emissions of nitrogen oxides from combustion of fossil fuel have increased globally at 1–2% per decade during this century, resulting in increased tropospheric concentrations particularly over continents in the lower atmosphere and in the flight corridors used by commercial aircraft. Nitrogen dioxide is an important absorber of visible solar radiation, and it could affect climate directly if tropospheric and stratospheric concentrations continue to increase.

Sulfur Gases

Emissions of sulfur dioxide and other gases can result in the formation of aerosols that can affect climate. Aerosols affect climate directly by absorption and scattering of solar radiation and indirectly by acting as cloud condensation nuclei (CCN). A variety of analyses indicate that human-related emissions of sulfur, and the resulting increased sulfuric acid concentrations in the troposphere, may be cooling the Northern Hemisphere sufficiently to compensate for much of the warming expected from greenhouse gases. Volcanic emissions can influence climate for short periods (1–3 years) through emissions of sulfur dioxide into the lower stratosphere.

More than half of the SO_2 emitted into the atmosphere comes from human-related sources, mainly from the combustion of coal and other fossil fuels. Most of these emissions occur in the Northern Hemisphere. Analyses indicate that anthropogenic emissions have grown dramatically during this century. Other SO_2 sources come from biomass burning, from volcanic eruptions, and from the oxidation of di-methylsulfide (DMS) and hydrogen sulfide (H_2S) in the atmosphere. DMS and H_2S are primarily produced in the oceans. Atmospheric SO_2 has a lifetime of less than a week, leading to formation of sulfuric acid and eventually to sulfate aerosol particles. Gas-to-particle conversion can also occur in cloud droplets; when precipitation does not occur soon, the evaporation of such droplets can then leave sulfate aerosols in the atmosphere.

During periods of low volcanic activity, carbonyl sulfide (COS) is thought to be responsible for the maintenance of the sulfuric aerosol layer found in the lower stratosphere. Natural emissions explain most of the COS in the present atmosphere, while the relatively long atmospheric lifetime (about 2 years) of COS explains why much of it reaches the stratosphere before its conversion to sulfuric acid aerosol. However, if sources of COS (or its precursor, CS_2) were to increase dramatically, the background aerosol layer concentration would increase, with significant implications for climate.

The Importance of Stratospheric Ozone

Ozone (O_3) is composed of three oxygen atoms and is a gas at atmospheric pressures and temperatures. Most of the ozone (about 90%) exists in the stratosphere, the layer of the atmosphere about 10–50 km above the Earth's surface. The remaining ozone is in the troposphere, the lower region of the atmosphere extending from the Earth's surface up to roughly 10 km at mid-latitudes and 16 km in the tropics. **Figure 4** shows a typical integrated column of ozone, referred to as the total ozone column, for various seasons based on satellite observations. Despite the fact that the primary production of ozone occurs in the tropics and the mid-latitudes, the largest amounts of ozone are found at high latitudes as a result of the pole-ward transport of ozone by atmospheric dynamical processes. The large decrease in ozone over springtime Antarctica, termed the "Antarctic ozone hole," can also be seen in **Figure 4**.

Ozone in the troposphere and stratosphere is chemically identical, but it has very different effects on life on the Earth depending on its location. Stratospheric ozone plays a beneficial role by absorbing UV-B, thus preventing biologically harmful levels of UV radiation from reaching the Earth's surface. It is the absorption of solar radiation by ozone that explains the increase in temperature with altitude in the stratosphere. Concerns about increased UV-B from the decreasing levels of ozone have been the driver for policy actions to protect the ozone layer.

Ozone is also a greenhouse gas, with a large infrared absorption band in the atmospheric window, at $9.6 \mu\text{m}$. It is the balance between the solar and infrared radiative processes that determines the net effect of ozone on climate. Increases in ozone in the stratosphere above about 30 km tend to decrease the surface temperature as a result of the increased absorption of solar radiation, effectively decreasing the solar energy that would otherwise warm the Earth's surface. Below 30 km, increases in ozone tend to increase the surface temperature, and the infrared greenhouse effect dominates in this region.

Closer to the Earth's surface, ozone displays its destructive side. Ozone is a strong oxidizer. Hence, direct exposure to high levels of ozone has toxic effects on human health and plants. Although ozone is a major component of photochemical smog in urban areas, this ozone is generally not thought to be a significant contributor to the global ozone budget. Balloon measurements suggest that tropospheric ozone at the global scale has been increasing.

Stratospheric Ozone Trends

Concentrations of ozone in the stratosphere result from chemical production and destruction processes in combination with transport processes. Production of ozone in the stratosphere results primarily from photodissociation of oxygen molecules. The destruction of ozone occurs mainly through catalytic reactions with other gases, such as chlorine and bromine. The total amount of ozone in the stratosphere will remain fairly constant (relative to the well-recognized seasonal variations) as long as there is no change in the destruction rate and the transport of ozone out of the

Figure 4 Integrated column of ozone, referred to as the total ozone column, for 2009 seasonal averages based on satellite observations. Total ozone values are often reported in Dobson units (DU). Typical values vary between 200 and 500 DU over the globe. The September measurements show the Antarctica ozone “hole.” Reproduced from 20 Questions and Answers section of World Meteorological Organization (2010) *Scientific Assessment of Ozone Depletion: 2009. Global Ozone Research and Monitoring Project, Report 52*. Geneva: World Meteorological Organization.

stratosphere. However, increasing inputs of chlorine and bromine into the stratosphere over the past few decades have changed this balance.

Measurements of ozone by satellite and ground-based instruments over the last several decades indicate that stratospheric ozone levels have decreased significantly. Amounts of ozone in the global atmosphere have decreased globally by more than 5% since about 1970 until the mid-1990s (the maximum decrease in ozone in 1992–1993 is in part related to the effects of sulfur emissions on heterogeneous chemistry in the stratosphere from the Mount Pinatubo eruption in 1991). **Figure 5** shows global averaged changes in ozone based on satellite and ground-based measurements. Satellite measurements began in late 1978, while a reasonably representative global network of ground-based stations has been in operation since the 1960s. In the data shown here, the seasonal variations and the effects of the variations in the solar flux due to the 11-year solar cycle have been removed (which would produce about a 1.2–1.5% variation from solar minimum to solar maximum).

Significant decreases in the total (integrated column of) ozone are found in both the Northern and Southern Hemispheres at the middle and high latitudes, with no significant change in the tropics. Much larger decreases in total ozone are found at latitudes greater than 60°, particularly in the Southern Hemisphere, as discussed later. Measurements indicate

that the total ozone column at mid-latitudes in the Northern Hemisphere has decreased by 1.3% per decade in the summer months and 2.7% per decade in the winter months since 1970. Satellite and ozonesonde (balloon) data sets indicate that ozone is particularly decreasing in the lower stratosphere, accounting for a major fraction of the trend in total ozone, although there is also significant ozone destruction occurring in the upper stratosphere. At the end of the ozone record in **Figure 5**, there is an upturn in ozone associated in part with the recovery from the effects of the Mount Pinatubo volcanic eruption in 1991. There are also indications that part of the increase in ozone is related to the effects of the Montreal Protocol to reduce levels of stratospheric chlorine.

Beginning in the late 1970s, a special phenomenon began to occur in the springtime over Antarctica, referred to as the Antarctic ozone “hole.” A large decrease in the total ozone, now greater than a 60% decrease relative to prehole levels, has been observed in the springtime (September to November) above Antarctica. Joe Farman of the British Antarctic Survey and coauthors documented this rapid springtime decrease in Antarctic ozone over the ozone measurement station at Halley Bay, Antarctica, attracting the attention of the scientific community. Decreases in the total ozone column of more than 50% were found, compared with historical values observed by both ground-based and satellite techniques. Measurements made in 1987 indicated that more than 95% of the ozone over

Figure 5 Deviations in total ozone with time relative to 1964–1979 from ground-based and satellite measurements. (a) shows the globally averaged trends and (b) shows the overall trend relative to latitude, showing that the largest changes in ozone have occurred at high latitudes. Reproduced from 20 Questions and Answers section of World Meteorological Organization (2010) *Scientific Assessment of Ozone Depletion: 2009. Global Ozone Research and Monitoring Project, Report 52*. Geneva: World Meteorological Organization.

Antarctica at altitudes from 13 to 22 km had disappeared during September and October. More recently, the Antarctic ozone holes since 1992 have been quite comparable, being the biggest (areal extent) and the deepest (minimum amounts of ozone overhead), with ozone being locally depleted by more than 99% between about 14 and 19 km in October. This continues through 2010, but the extent of the Antarctic ozone decrease should lessen over the coming decades.

Causes and Consequences of Stratospheric Ozone Depletion

The connection between potential environmental effects and man-made CFCs was first raised by Dr. Mario Molina and Dr. Sherwood Rowland in 1974, when they suggested that chlorine from these compounds could destroy stratospheric ozone. Research findings since then have continued to support the significant role that these compounds play in affecting the global distribution of ozone. In addition, it is recognized that

other gases containing chlorine and bromine, which are even more reactive with O_3 than chlorine, are also affecting ozone. To a lesser extent, the increasing concentrations of other gases like CO_2 , CH_4 , and N_2O are also affecting stratospheric ozone.

The inverse relationship between changes in ozone and UV-B is well established by both theoretical analyses and observations. A number of studies have shown that the corresponding increase in UV-B at the ground resulting from ozone depletion can lead to increased incidences of skin cancers, cataracts, and other effects on humans and animals.

The recognition of the deleterious effect of chlorine and bromine on ozone spawned international action to restrict the production and use of CFCs and halons to protect stratospheric ozone. These included the 1987 Montreal Protocol on Substances That Deplete the Ozone Layer and the subsequent 1990 London Amendment, 1992 Copenhagen Amendment, and the 1997 Montreal Amendment. The agreements initially called for reduction of CFC consumption in developed countries. A November 1992 meeting of the United Nations Environment Programme held in Copenhagen resulted in substantial modifications to the protocol because of the large observed decrease in ozone, and called for the phase-out of CFCs, carbon tetrachloride (CCl_4), and methyl chloroform (CH_3CCl_3) by 1996 in developed countries. As part of this, the USA, through the Clean Air Act, has also eliminated the production and import of these chemicals. Production of these compounds is to be totally phased out in developing countries by 2010, while production of halons in developed countries was stopped in 1994. Human-related production and emissions of methyl bromide are not to increase after 1994 in developed countries, with total elimination by 2005.

Projected Trends in Ozone

Projected changes in globally averaged total ozone, using several assumptions about future emissions of CFCs, halons, and their replacements, have been evaluated using models of atmospheric processes. With the original Montreal Protocol provisions, there would still have been a significant reduction in total ozone, as much as 15% by 2050 relative to 1980 levels, according to some analyses. It is only under the London and Copenhagen Amendments and more recent provisions, which call for the complete phase-out of CFCs and halons and other halocarbons, that the ozone reduction trend is reversed. The largest ozone reductions are analyzed to have been reached in the late 1990s. After this, ozone begins to recover, although it is not until about 2050 or later that the 1980 level of global total ozone would again be expected (and more likely, much later over Antarctica). Thus, according to these models, it will roughly be the middle of the century before the chlorine and bromine in the stratosphere are reduced to levels corresponding to those when the Antarctic ozone "hole" first began. Also, without any control measures and assuming unfettered growth, the global mean total column ozone would decrease about 30% by 2050, decreasing further with time. Because of the increasing levels of CO_2 , CH_4 , and N_2O , which can have either radiative or chemistry effects on ozone, the distribution of ozone in the future stratosphere may not look like that in 1980 at any time this century.

Air Pollutants in the Lower Atmosphere

The elevated concentration of oxidants in urban regions is a difficult problem in many parts of the world. In the USA, progressively tighter emissions controls have been implemented since the late 1970s to control production of ozone. Most of these controls have been aimed at emissions of NO_x and VOCs, particularly the former. Nonetheless, many urban areas still fail to meet the federal standards. In addition, there is growing concern that enhanced levels of ozone concentrations in rural areas downwind of urban areas are resulting in harmful effects on agricultural and forest ecosystems. Part of the difficulty is understanding how emissions of hydrocarbons from the biosphere affect ozone levels in urban areas.

The Future and Atmospheric Gases

Changes in climate associated with increasing concentrations of greenhouse gases could have significant effects on the biosphere and on biodiversity. Corresponding changes in the biosphere could affect biogeochemical cycles and the sources and sinks of atmospheric gases, leading to further changes in the climate. Such interactions with the biosphere and with biodiversity are inadequately considered in current climate projections. The effects of such interactions require much more study.

Stratospheric ozone levels should largely recover at mid-latitudes by mid-century. However, the timing of this recovery will largely depend on the emissions of halocarbons and on the emissions of other gases that influence stratospheric chemistry. Changes in the oxidative capacity could also change the amounts of gases reaching the stratosphere and thus the rate of and extent of recovery. Climate change would also likely influence stratospheric temperature and winds, thus further affecting the rate of ozone recovery. The long-term

impacts of the reduced levels of ozone on the biosphere and on biodiversity remain poorly understood.

Attempts to control pollution in urban regions continue to increase. However, there is still much to learn before such controls can be fully effective. The US National Academy of Sciences has stated that too little is known about the transport and deposition of atmospheric gases, including toxics and nutrients, to the biosphere and their interaction with biota. Further study of the rates of chemical exchange between the atmosphere and ecosystems will provide better quantitative estimates of atmospheric chemical impacts on the biosphere and biospheric emissions to the atmosphere.

Carbon Cycle

John Grace, University of Edinburgh, Edinburgh, UK

Published by Elsevier Inc.

Glossary

Autotrophic respiration The respiration of photosynthetic organisms.

Biomass The mass of biological material after the removal of water by oven-drying at 70–100 °C, often expressed as mass per area of ground surface.

Flux The flow of any material measured as quantity per area per unit of time.

Gigatons of carbon (Gt C) Billion (10^9) tonnes of carbon or 3.67 billion tonnes of CO_2 .

Hectare (ha) $1 \text{ ha} = 10^4 \text{ m}^2 = 0.01 \text{ km}^2$

Heterotrophic respiration The respiration of all those life forms that feed on organic matter, including bacteria, fungi, and animals.

Sink A component of the carbon cycle that is a net accumulator of carbon annually, such as the ocean or the forests.

The carbon cycle is the circulation of carbon atoms between the ocean, land, and atmosphere by physical, chemical, and biological processes. Living organisms are of great importance in the carbon cycle, because life on planet Earth is comprised of carbon compounds such as proteins, carbohydrates, and lipids. Thus, the cycle is one of many *biogeochemical cycles*, whereby organisms re-use vital elements such as carbon, nitrogen, sulfur, and phosphorus.

The important natural processes that circulate carbon between the atmosphere and the surface of the planet by living organisms are photosynthesis and respiration, whereas the significant nonliving processes (physical and chemical) are dissolution of gases in water, and the weathering of rocks.

The carbon cycle may be considered over either geological time frames (millions of years), or over recent years, decades, and centuries. In this article, we focus on the recent period and we speculate about the future behavior of the carbon cycle over the coming decades.

The carbon cycle has been perturbed by human activities. Since the Industrial Revolution (1760–1830), the widespread use of fossil carbon for energy, such as coal, oil and gas, has led to a substantial increase in the CO_2 concentration in the atmosphere. Moreover, biomass carbon is returned to the atmosphere as CO_2 when forests are cleared and replaced by agriculture. There is now widespread realization among national governments and among scientists that these anthropogenic emissions of CO_2 and other trace gases are increasing the greenhouse effect and causing global warming. At the same time, it has been discovered that the land surface and the ocean absorb a substantial fraction of the fossil fuel emissions. However, these are uncertain sinks, and their uptake of CO_2 may not persist for much longer. Consequently, there has been intense research activity in this area of science, and efforts to manage the carbon cycle to limit the greenhouse effect and thus protect the climate.

Outline

The carbon cycle is changing as a result of an increasing rate of fossil fuel burning and a continuing high rate of deforestation.

The Kyoto Protocol has failed to limit the rise in carbon dioxide in the atmosphere. The author outlines some of the critical processes in the carbon cycle, and the nature of and future of the natural sinks for CO_2 . The author discusses how the carbon cycle might be managed to limit the rise of CO_2 .

General Features

Figure 1 summarizes current knowledge of the carbon cycle, showing the size of the carbon reservoirs and the magnitude and direction of the annual exchanges between them. The carbon cycle is said to be *out of balance* because the concentration in the atmosphere is currently increasing by about 4 Gt C annum⁻¹. Records of CO_2 trapped as bubbles in old ice show that in the half-million years before the Industrial Revolution, the CO_2 concentration varied only slightly in the range 180–325 ppm in cycles that correspond to periods of glaciation. However, in the past 50 years, when precise physical measurements have been possible, the concentration has increased rapidly and inexorably from 315 ppm to the present-day (2011) value of 390 ppm (**Figure 2**), diverging from the pattern that is observed so clearly in the ice cores. Here, the author discusses the processes involved in the flows (fluxes) represented in **Figure 1**.

The Land Sink

In a steady-state world, before industrialization, it is presumed that the uptake of CO_2 from the atmosphere by the process of photosynthesis was more or less in balance with the losses from respiration and fire. If we simplify the gas exchanges by allowing glucose, $\text{C}_6\text{H}_{12}\text{O}_6$, to represent biomass, we may write an equation to express this steady state:

Here, the double arrow $\leftrightarrow$ represents a reversible reaction. Photosynthesis proceeds from left to right. In photosynthesis, green plants absorb the sun's energy and use it to split water. The hydrogen from the water is the reducing power to turn

Figure 1 Global carbon cycle, updated for 2010. The term for fossil fuels includes emissions from cement manufacture. Data for emissions have the following uncertainty: fossil fuels 8.4 ± 0.5 and land-use change 1.2 ± 0.7 . Land and ocean sinks may vary from year to year, especially the land sink. Data for stocks on the land and in the ocean are very uncertain.

Figure 2 Carbon dioxide concentrations in parts per million, measured at Mauna Loa. Data source: Dr. Pieter Tans, NOAA/ESRL (www.esrl.noaa.gov/gmd/ccgg/trends/).

CO₂ into glucose. The oxygen escapes into the atmosphere as a byproduct, and over some 4 billion years, this is the process that gives Earth such an unusual atmosphere, with a high oxygen concentration. Likewise, respiration and fire are represented by running the equation from right to left. Equation [1] is merely a summary: in practice, photosynthesis and respiration consist of many reactions, biophysical and biochemical.

We know there is currently a land sink from various observational studies. First, application of the micrometeorological method of eddy covariance, at sites all over the world, has shown that most ecosystems, and forests in particular, are

taking up more CO₂ by photosynthesis than they are losing in respiration (Luyssaert *et al.*, 2007). This sink effect seems to be most significant in tropical rain forests and in the north temperate zone. Surprisingly, even old forests have been shown to be active carbon sinks (Luyssaert *et al.*, 2008). The conclusion that the terrestrial ecosystems are a sink may also be drawn from analysis of the CO₂ concentrations in the atmosphere (Rodenbeck *et al.*, 2003): forested areas (north America and the humid tropics) tend to have lower concentrations of CO₂ in the air above them. After making due allowance for atmospheric mixing and biomass burning, it is possible to infer the sink strengths over the land and sea. Tropical and north temperate forests are the strongest sinks (Rodenbeck *et al.*, 2003). Further evidence for the existence of a terrestrial carbon sink comes from repeated inventories of the biomass in relatively undisturbed forests, both tropical and temperate (Lewis *et al.*, 2009; Luyssaert *et al.*, 2008). The biomass inventory method tells us nothing about CO₂ from the soil, but it does show that more carbon is being stored as biomass per hectare than in former times, and does provide an estimate that is broadly consistent with the other data sources.

There are a number of explanations for the imbalance in the carbon cycle. First, CO₂ is rising rapidly and it is known from many other studies that photosynthesis is usually stimulated by high CO₂ (Ellsworth *et al.*, 2004). Second, the deposition from atmosphere to land of active nitrogen (NH₄⁺, NO₃⁻) acts as a fertilizer and increases the productivity of vegetation (Magnani *et al.*, 2007). This active nitrogen is widely regarded as a pollutant, as it may change the species composition of ecosystems, and it may impact negatively on biodiversity because N-fertilization always favors the more

competitive plant species against others. Moreover, nitric acid is formed from NO_3^- and this contributes to the acidification of water. However, alongside these undoubted disbenefits, it does seem that nitrogen deposition has a significant benefit in terms of its effects on the land sink. 'Natural' or preindustrial N-deposition is just a few $\text{kg ha}^{-1} \text{ annum}^{-1}$ whereas industrialized parts of the world receive up to $40 \text{ kg ha}^{-1} \text{ annum}^{-1}$. Typical agricultural applications of ammonium nitrate fertilizer, for rapid plant growth, are $80\text{--}150 \text{ kg ha}^{-1} \text{ annum}^{-1}$. There have been many attempts to model this interplay between fertilization by CO_2 and active nitrogen (Lloyd and Farquhar 1996), although the reasons for the sharp increase in sink strength are not fully understood and still represent an active field of research.

Photosynthesis is believed to remove as much as $120 \text{ Gt C annum}^{-1}$ from the atmosphere, but around 60 of this is "lost" again as plant (autotrophic) respiration. The difference between these two numbers represents the rate at which the world's vegetation is producing organic matter (the NPP, Net Primary Productivity). However, as soon as it is produced, it begins to be consumed by animals and microbes (known as the heterotrophs). Approximately 60 is emitted as heterotrophic respiration (the respiration of heterotrophic organisms, including microbial decomposition and animal respiration). Data from a large number of actual sites may be seen in Luyssaert *et al.* (2007).

The land sink occurs because photosynthesis exceeds the sum of autotrophic and heterotrophic respiration. Annually, this excess is now about 2.4 Gt C . This means that the terrestrial ecosystems of the world are removing about 29% of the carbon released in fossil fuel burning.

Transport from Land to Ocean

Not all the carbon captured by terrestrial systems is retained on the land. Estimates of the mass of carbon carried away are hard to obtain from the limited amount of work carried out so far, and the huge diversity of river systems to be considered. Here, the author uses a recent review paper to provide the estimate in Figure 1. According to Cole *et al.* (2007), inland waters receive $1.9 \text{ Gt carbon annually}$ from the land, of which 0.2 is buried as sediment and perhaps 0.8 is returned from rivers to the atmosphere as CO_2 and CH_4 . The remaining 0.9 Gt carbon enters the ocean, where some of it remains for a very long time. This fraction of plant material that has survived the journey by river is likely to contain the chemically and biologically resistant parts of plants, notably plant cuticle, pollen, and wood fibers.

The Ocean Sink

We may consider two types of ocean sink: the solubility sink and the biological pump. The solubility sink is simply the dissolution of CO_2 in water; at 10°C , 1.16 m^3 of the gas dissolves in a cubic meter of water. In solution, there is an equilibrium mixture of carbonic acid and bicarbonate and carbonate ions:

The process of dissolution is temperature sensitive, according to Henry's Law. Gases are less soluble in warm water than in cold: at 0°C 3.4 g CO_2 dissolves in 1 kg of water, whereas at 10°C , the corresponding value is 2.5 and at 20°C the value is 1.7.

In those parts of the ocean where the water surface has a low concentration of dissolved CO_2 and is also cold and down-welling, the reaction proceeds strongly from left to right, i.e., CO_2 from the atmosphere dissolves in unsaturated water. Obviously, this rate will increase as the atmospheric CO_2 concentration increases. In other parts of the ocean where surface waters are warm, upwelling and supersaturated with CO_2 , as in the tropics, dissolution occurs (i.e., the reaction runs from right to left).

From eqn [1], it is clear that dissolution tends to increase the acidity of the ocean. Observational data show the scale of this effect. From 1700 to the present, the northern and southern oceans have decreased in pH by 0.1 units of pH. There are fears that this may impact on the physiology of marine organisms, especially those that form carbonate shells.

Superimposed on the chemical solubility is the ecology of marine organisms. They remove dissolved carbon to synthesize CaCO_3 as shells in the case of invertebrates and bones in the case of vertebrates. These organisms are connected in food chains. When the organisms die, the shells and bones sink to the sea bed under the influence of gravity, thus removing carbon from the surface layers of the ocean and maintaining the concentration gradient, so that eqn [1] tends to proceed from left to right because the products (carbonates) are removed. This is referred to as the biological pump.

The ocean sink removes about 2.3 Gt C from the atmosphere each year, about 27% of the carbon released in fossil fuel burning.

Deforestation Flux

The world was once much more heavily forested than it is today. For example, England's forest cover was reduced from 90% to 20% by Roman times, and then declined to 5% by 1350, the time of the Black Death. European deforestation was rapid in the period of population growth before the Industrial Revolution. Then, land was needed for agriculture and timber was needed for dwellings and ships. Empire-building and the colonization of north America and Australia initiated further great waves of deforestation.

Deforestation in the last half-century has been in the humid tropics. Peninsular Malaysia's forest cover declined from 74% to 40% in the period 1958–1990. Currently, the deforestation rate in Indonesia and South America is a cause of great concern, especially because of the biodiversity these forests contain.

The causes of deforestation vary geographically. In Latin America and Africa, the main driver has been the planned clearance of forest to make way for agriculture, and sometimes simply the unplanned expansion of agriculture onto forested lands (Geist and Lambin, 2002). In Southeast Asia the drivers are somewhat different. There, the Dipterocarp forests contain excellent timber and have often been destroyed or degraded by logging. However, the new driver in SE Asia is clearance of

forest to make way for oil palm, *Elaeis guineensis*, a lucrative crop. Its product, palm oil, is incorporated into diesel fuel for vehicles.

Deforestation is often defined as the removal of a forest or stand of trees, where the land is thereafter converted to a nonforest use, frequently agriculture. Once an agricultural system is formed, the biomass carbon declines to a few tonnes per hectare, and the soil organic carbon also declines, although slowly. However, in addition to complete deforestation, the degradation of forest is highly significant, both for carbon and for biodiversity. In its degraded state, the structure and microclimate is changed and so is the species composition. Moreover, degraded forest is inherently more susceptible to complete deforestation.

The pressure on forests is related to a country's stage of economic development (Figure 3). In this framework, we trace a pattern of deforestation from the initial point where forest cover is high and human populations are low. As the population grows, forest is cleared to provide land for crops. For economic reasons, such countries encourage logging (or these days, perhaps biofuel production from oil palm plantations), which accelerates deforestation. At a later stage, when development of urban centers is more advanced, forests become scarcer and more valued so that a transition point is reached. This seems to occur when the GDP is greater than

US \$5000 per person. At this point, deforestation is reduced and may even be reversed.

Tropical deforestation is high and its measurement remains controversial (Achard *et al.*, 2002; Hansen *et al.*, 2010); country-scale estimates such as those oft-quoted from the Food and Agriculture Organization (FAO) are sometimes disputed and do not always agree with data from satellites. Ultimately, the best estimates will be those from satellite remote sensing, which detects the conversion from forest to nonforest, pioneered by the Brazilian PRODES project from the 1970s. Most conventional satellite data, using optical remote sensing, fail to record forest degradation produced by logging, but advances under radar remote sensing provide prospects of measuring the biomass of any forest in any weather conditions and operating by night and by day, thus achieving good imagery many times per year and detecting quite slight disturbances (Mitchard *et al.*, 2009). Recent assessments (van der Werf *et al.*, 2009, 2010) suggest that CO₂ emissions from deforestation and forest degradation (excluding peatland emissions) are now about 1.2 Gt C annum⁻¹. The global value is found by multiplying the area of forest lost by the estimate of the changes in carbon stock when the land is covered from forest to agriculture. Both the areas and the stock change have associated error in the order of 20%, and so the figure of 1.2 is uncertain.

Figure 3 Hypothetic decline in forest cover associated with national development, showing where a few specific countries lie on the curve.

Figure 4 Regional carbon stocks in forests (Gt of carbon) in 1990 (purple), 2000 (brown) and 2010 (green). Regions are: a, Africa; b, Asia and the Pacific; c, Europe; d, South America; e, Near East; f, North America.

The FAO data set (FAO, 2011) reveals major geographical variations in both the rate of deforestation and the reasons for land-use change (Figure 4). The data are assembled annually from information returned by most countries of the world. It should be noted that the FAO definition (forest cover more than 10% and an area of more than 0.5 ha) is different from that which would generally be used in the remote-sensing community, and that most of the respondent countries perform forest inventories infrequently, and may thus submit estimates that will subsequently be shown to be unreliable (Table 1).

This $1.2 \text{ Gt C annum}^{-1}$ from forest clearance constitutes 14% of the total anthropogenic emissions. It is sometimes said that this percentage is much higher. It used to be, but fossil fuel burning has increased very rapidly since 2000, and estimates of global deforestation rates have been reduced somewhat, partly because Brazil and Indonesia have reduced their deforestation rate.

Fossil Fuel Burning

Fossil fuel emissions have increased sharply since the year 2000 (Figure 5), partly because of the failure of most signatories to the Kyoto Protocol to limit their CO_2 emissions, and partly because of the extremely rapid industrial growth of China and India (Friedlingstein *et al.*, 2010). The world's largest emitting country is now China, followed by the USA and then India (Peters *et al.*, 2012). The population of both China and India exceeds 1 billion, and their per capita emissions are increasing rapidly. However, they are still far behind other countries on emissions per head of population. China's per capita emissions are about $1.2 \text{ tC capita}^{-1} \text{ annum}^{-1}$ whereas Saudi Arabia, USA, Australia and Canada all exceed $4 \text{ tC capita}^{-1} \text{ annum}^{-1}$ (Peters *et al.*, 2012).

Known stocks of fossil fuels on a world scale are enough to sustain current emissions for about a century (Figure 1). The prices of coal, oil, and gas are likely to rise abruptly as stocks dwindle, although fresh supplies may be found as exploration continues. Gas and oil reserves are substantially less than those of coal. Very large stocks of coal remain in Australia, China, and Russia. Added to the conventional fossil fuels (coal, oil, gas) we should not overlook other possible supplies – tar sands and methane clathrate.

Tar sand is a mixture of clay, sand, water, and highly viscous oil, and is especially abundant in Canada and Venezuela. World stocks are thought to exceed two trillion barrels (about 170 Gt C). These stocks are dwarfed by methane clathrate. The term 'methane clathrate' refers to a family of loosely bound molecular associations of methane with water. These compounds exist in stable form in marine sediments, but when brought to normal atmospheric pressure, they decompose to release methane. Some estimates of the quantity of carbon as clathrate are as high as 5000 Gt C , but the resource is widely dispersed, unlike coal, oil and gas, and thus only a small fraction is ever likely to be extracted.

Carbon as clathrates and tar sands is not considered in the fossil fuel stocks in Figure 1, which is why this pool is shown as being substantially smaller than illustrated in other representations of the carbon cycle (IPCC 2007).

Other Sources and Sinks of CO₂

If the carbon cycle were redrawn to cover the whole of the Earth's history, it would include slower processes that become highly significant when accumulated over geologic time scales.

Carbonic acid reacts slowly with minerals in several ways, as illustrated in the following examples. Such processes are collectively called *weathering*. In this case, bicarbonate reacts with feldspar to form the clay kaolinite:

In the second example calcium carbonate is weathered and once more bicarbonate is produced:

In warm shallow seas and elsewhere, large deposits of calcium and magnesium carbonate were formed over geological time scales from bicarbonate, most of them having been deposited by living organisms. Many groups of microscopic and macroscopic organisms form these carbonates. In the Paleozoic (251–542 million years ago), the most abundant carbonate formers were corals, trilobites, brachiopods, bryozoans, and crinoids. Later, the dominant organisms involved in this process were coccolithophores, foraminifera, red algae, bivalves, and gastropods. Some very large deposits of carbonate rocks have uncertain origins, for example, dolomite, calcium magnesium carbonate $\text{CaMg}(\text{CO}_3)_2$, which gives its name to the Dolomite mountain range in north-east Italy.

Carbonate rock is subducted over geological time scales to become part of the oceanic crust. This carbonate may react with silica (SiO_2) to form CO_2 , which is released back into the atmosphere in volcanic eruptions. In this way, the geologic carbon cycle is completed. Volcanic activity has not been constant, but over recent times, the rate of CO₂ emission estimated by scaling up data from a small number of volcanoes is very small: only 0.07 Gt C per year (Gerlach, 1991). During periods of intense volcanism, volcanoes are capable of influencing the climate system because of the large quantities of sulfate (and other) aerosols they emit. The aerosols remain in the atmosphere for a few years; this may cause cooling, and the enhanced aerosols scatter solar radiation, thus increasing the diffuse fraction of solar radiation that reaches the land and enhancing the rate of photosynthesis.

Other Volatile Carbon Compounds (VOCs)

Methane is a greenhouse gas emitted from both natural and anthropogenic sources. The natural sources are all those places

where organic matter is microbially decomposed in the absence of oxygen, including wetlands and the guts of animals. At times, there may also be efflux from ocean to atmosphere from the decomposition of clathrates. Significant methane emissions are reported from leaves under aerobic conditions, produced by the action of sunlight on pectin, the material that binds plant cells together (McLeod *et al.*, 2008). The anthropogenic sources include fossil fuel burning, mining, burning, and livestock. The gas is 72 times more active than CO₂ in absorbing outgoing thermal radiation, when assessed over 20 years. Its lifetime in the atmosphere is only about 10 years, as it is consumed by various sinks, whereby it is converted to CO₂. The concentration in the atmosphere increased rather rapidly from 1850, when it was about 0.8 ppm, but since 1995 the growth rate has slowed, and now the concentration is beginning to level off at about 1.8 ppm.

The balance between sources and sinks of methane is still uncertain (Table 2). The primary sink in the atmosphere is the hydroxyl radical OH, which is formed by photochemical reactions in the atmosphere. In the soil and probably also on leaves, communities of methanotrophic bacteria consume methane and release CO₂.

Plants emit many volatile organic compounds, some of which give them their characteristic smells, well known in the perfume industry.

Isoprene (C₅H₈) is the predominant VOC emitted by many broadleaved species including poplar, oak, willow, sycamore, and eucalyptus. The emissions occur in the daylight, especially when plants are stressed, as for example by drought. Global production may be as high as 0.5 Gt C per year (Guenther *et al.*, 2006). Isoprenes are the building blocks that are responsible for the biosynthesis by plants of the familiar terpenes, which can be represented as (C₅H₈)_{*n*}. Isoprene and terpenes are implicated in the seeding of clouds, and so may play a role in regulating global temperatures (Meir *et al.*, 2006). When *n* = 2, the compounds are volatile and include many of the compounds that give coniferous species their characteristic smell. When *n* is large, the compounds are resinous and when *n* is very large (molecular weight 100,000 to 1,000,000) we have rubber.

There are many anthropogenic VOCs, for example, compounds that are used as solvents in paint and in cleaning fluids. Poorly tuned automobile engines emit VOCs in significant quantities. VOCs become highly reactive in sunlight, so that in cities in sunny climes such as Los Angeles and Rome we experience photochemical smog when aerosol particles, ground-level ozone and oxides of nitrogen from motor cars coexist.

Lifetime of CO₂ in the Atmosphere

Estimation of the lifetime of CO₂ in the atmosphere is a significant challenge to our understanding of the basic processes. Although photosynthesis removes CO₂ at a rate of some 120 Gt C per year from the atmospheric pool of 700 Gt C, much of this carbon is released almost immediately as autotrophic respiration. Some is stored in relatively long-lived materials such as wood and soil organic matter, and it will be released in hundreds or perhaps thousands of years for some compounds (e.g., wood trapped in bogs decomposes very slowly to release methane). Likewise, when CO₂ dissolves in the ocean, it may be released rather quickly from the surface layers, or it may be circulated to the deep abyss to reemerge a century or more later. A small fraction is incorporated into carbonates and enters a geological reservoir, which is long term but also not necessarily a permanent store. An analysis by Archer *et al.* (2009) suggests that 20–35% of any emissions would remain in the atmosphere after equilibration with the ocean (a period of 2–20 centuries). A similar argument applies to any attempt to remove CO₂ by geo-engineering; efflux from the ocean would continue for some time after CO₂ emissions are eliminated and tend to slow down any attempt to “scrub” the atmosphere.

Managing the Carbon Cycle

To avoid further global warming, it is essential to find other sources of energy. The world's energy demand increased substantially every year until 2009, when it declined, along with CO₂ emissions (Figure 5). The decline was the result of the economic recession and is likely to be temporary (Peters *et al.*, 2012). The challenge is to enable an increase in energy supply to countries that are still developing economically, whilst reducing or eliminating the emission of greenhouse gases

including CO₂. This seemingly impossible challenge has been approached by the United Nations and national governments in a number of ways.

Responding to concerns that human activities are increasing atmospheric concentrations of greenhouse gases such as carbon dioxide and methane to levels that threaten to cause damaging global warming, most nations of the world signed the United Nations Framework Convention on Climate Change in 1992. They promised to work toward the stabilization of emissions. Following subsequent negotiations, the Kyoto Protocol (in late 1997) committed nations to legally binding reductions in emissions of six greenhouse gases: carbon dioxide, methane, nitrous oxide, hydrofluorocarbons, perfluorocarbons, and sulfur hexafluoride. These reductions were to be counted from 1990 to the “commitment period” between 2008 and 2012, and should have limited the emissions of 37 industrialized countries and the European community. However, most of these countries have increased their emissions despite their “legally binding” pledge to reduce them. Thus, the Protocol has failed, and at the time of writing (April 2012) nothing has been agreed to replace it.

Various countries have, however, passed legislation to limit their own emissions. For example, the UK government’s Climate Change Act states: “It is the duty of the Secretary of State to ensure that the net UK carbon account for the year 2050 is at least 80% lower than the 1990 baseline”. Other European countries have similar legislation, passed or in preparation. However, in the USA, no such legislation exists, nor in China and India.

The issue of how to reduce emissions has been considered by the Intergovernmental Panel on Climate Change (IPCC) in its Fourth Assessment Report published in 2007. This 850-page document is freely available on the internet.

To mitigate climate change by moving from fossil-fuel-based energy to other forms of energy will be expensive and the task requires long-term planning and investment. The *Stern Review on the Economics of Climate Change* was an attempt by the UK government to analyze the problem and to outline an appropriate course of action. Most importantly, the study estimated the scale of the investment needed to limit CO₂ concentrations so as to avoid dangerous climate warming. In June 2008, Stern increased the estimate for the annual cost of achieving stabilization between 500 and 550 ppm CO₂ to 2% of the global GDP to account for faster than expected climate change (Stern, 2006). Since then, other economists have challenged the underlying assumptions made by Stern, and some place the cost as high as 10%.

Carbon Capture and Storage

Carbon Capture and Storage is a geo-engineering approach that applies to large carbon dioxide sources, such as power stations and some chemical facilities. The idea is to capture the CO₂ at the source of emission so that it cannot enter the atmosphere. This might be done by injecting the gas into suitable geological reservoirs, usually envisioned as sedimentary rocks that have previously been filled with oil or natural gas (IPCC, 2005). The engineering effort required for this is substantial, but much of the technology has already been developed by the extraction industry. Another approach

would be to inject CO₂ directly into the deep ocean, where it is expected to remain for millennia. A third approach currently being investigated is to use large-scale industrial chemistry to form carbonate rocks.

The stability of the storage is an environmental concern, and also a health and safety issue. CO₂ is highly toxic to humans and other animals when its concentration exceeds 10%, as we see at locations on the Earth where CO₂ escapes from geological sources such as Lake Nyos in NW Cameroon, where 1800 people were killed in 1986 when a “bubble” of 1.6 million tonnes of CO₂ was ejected by the lake. Capture from a coal or a gas-fired power station is estimated to cost US \$15–75 per tonne of CO₂ captured. This high price (compared with a few dollars per tonne for forest plantations) is partly because of the “energy penalty” associated with compressing and piping the gas to storage reservoirs. Nevertheless, by 2010, nine industrial-scale storage projects were in operation, and many more are planned. It is generally considered that CCS has the potential to sequester more CO₂ than any other single man-made activity.

Iron Fertilization of the Ocean

The productivity of many parts of the ocean is limited by the availability of iron. This has been shown by experimental addition to the ocean of soluble salts of iron and subsequent evaluation of the phytoplankton populations. Thus, it might be possible to enhance the ocean’s biological pump using iron additions. Probably, one-third of the ocean is iron limited, and might be expected to sink more carbon if it could be fertilized. This prospect has attracted considerable attention, especially in the commercial sector, as substantial quantities of carbon could be captured, at least in theory. These quantities might be tradable in the carbon offset market. It is not clear, however, how well this would work, despite several major international research projects having been completed. The issues are: (i) if there is a sudden stimulation of fast-growing phytoplankton, it does not necessarily follow that other biota feeding on the plankton would increase. If not, the phytoplankton might simply die and decompose, returning much of the carbon to the atmosphere; (ii) some parts of the ocean are known to be deficient in other nutrients and iron. Silicon is sometimes deficient, essential for some phytoplankton; (iii) measurement of the amount of carbon that is indeed sequestered for a long term would be very difficult.

The iron fertilization option is still of interest, but probably not as easy as was thought in the 1990s when experimentation began (Watson *et al.*, 2008).

Managing Soil Respiration

Soil is a complex and highly variable mixture of mineral and organic material, formed naturally over thousands of years. The minerals are derived from particles of rock, altered by chemical, and physical processes. They include chemically rather active materials such as clay, which stores cations and exchanges them with the soil solution and coats particles of organic material. Much of the organic material is derived from dead plant and animal material, and is subject to biological

decay through the activities of fungi and bacteria that feed on them. Living organisms such as these produce carbon dioxide through respiration; it accumulates in the pores of the soil, eventually diffusing to the atmosphere. The other source of respired CO_2 in the soil is plant roots. Thus, CO_2 diffuses from the soil surface to the atmosphere. Its rate can be measured using sensitive instruments and is found to be between 2 and $10 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$, depending on the location and the environment (temperature and moisture are the main variables). Globally, the heterotrophic part of soil respiration alone is thought to be many times greater than fossil fuel emissions, but as we have seen (*see* The Land Sink), the respiratory “loss” terms are approximately balanced by the photosynthetic “gains.”

Soil respiration increases more or less exponentially with temperature, but only as long as substrate is continuously added to the soil. The exponential relationship is best seen in short-term experiments (lasting hours or days). In long-term experiments (years), the enhanced rate of respiration in warmed plots is not maintained, presumably because the substrate (readily decomposable organic matter) becomes depleted.

The management of soils may considerably influence their carbon storage capacity. One of the longest experiments in soil management ever undertaken is at the Rothamsted Experimental Station in central England. Wheat has been grown in the Broadbalk field since 1843, while the land has been subject to different applications of fertilizer or manure (Gregory *et al.*, 2009). It is found that soil that has been fertilized by adding farmyard manure has three times more stored carbon than soil that has been dressed with a chemical fertilizer. The reason for this difference is that plant residues take a long time to decompose; farmyard manure contains residues of grasses, some of which are highly resistant to decay. These residues remain in the soil for decades, or in cold climates, centuries.

Another way to store carbon in soils is to bury charred biomass, known as biochar. This is mostly composed of elemental carbon (charcoal) but contains many other elements derived from the biomass, including nitrogen. Charcoal is particularly resistant to decay and remains in the soil for a very long time. It is widely believed that the dark soils found in several parts of S America (in Brazil, *Terra Preta do Indio*) were mostly created by the use of biochar by pre-Columbian Indians from 500 to 2500 years B.P.

A third way to manage soil as a carbon store is to avoid too much cultivation. When soil is disturbed by a plough, roots are cut and organic material that has been long buried is brought to the surface, where it may be more easily decomposed. Moreover, the increased drainage capacity of the cultivated soil may increase microbial growth. However, this expectation is not always borne out by field trials. West and Wilfred (2002) reviewed 67 long-term experiments on the effect of no-tillage on soil carbon storage and found cases where the results were the other way round. However, on average, the storage of carbon was increased by $57 \pm 14 \text{ gC m}^{-2} \text{ annum}^{-1}$. If we assume that the sites in that study were truly representative of arable land, and further assume that arable land of the world is 30 million km^2 , we see that the potential exists to sequester a global total of 1.7 Gt C each year. In some soils, however, this practice would reduce the agricultural yield substantially.

Planting and Managing Forests

In temperate regions of the world, plantations of fast-growing trees such as willows and poplars are capable of accumulating carbon in biomass and soil at rates from 2 to 10 tonnes of carbon per hectare per year. In tropical regions, Eucalyptus and probably many other trees can exceed this as long as there is adequate water supply. However, generally, these are rates quoted for the early phase of growth and without subtracting carbon losses from heterotrophic respiration (mostly ‘soil respiration’). Over the life time of the plantation, and taking into account carbon losses at establishment and harvesting (Kowalski *et al.*, 2004), the rate is much less. The fast-growing species, *Picea sitchensis* (Sitka spruce), has been introduced into the UK from North America and is widely grown on poor soils in wet and windy places. Its rate of carbon accumulation over a crop rotation of 40 years is $2\text{--}4 \text{ tC ha}^{-1} \text{ annum}^{-1}$ even without fertilizer.

The rate of growth of trees can often be increased by adding fertilizer. In temperate and boreal regions, nitrogen generally limits growth and most tree crops in these zones respond to nitrogen fertilizer. In the tropics, nitrogen may sometimes limit growth, but in the humid tropics phosphorus is often rate-limiting. When nitrogen fertilizer is used anywhere, there is likely to be enhanced emissions of nitrous oxide from the soil. This gas has a Global Warming Potential, which is 289 times higher than carbon dioxide when assessed over 20 years, and so where the purpose of the tree crop is to reduce the rate of accumulation of greenhouse gases in the atmosphere, fertilizer should be avoided. This issue has loomed large in the debate about biofuels. In ‘first-generation biofuels’, it is usual to stimulate plant growth by using nitrogenous fertilizer, but heavy dosage results in emissions of N_2O from the soil. The contribution this makes to warming the atmosphere may be more than that saved from avoiding the use of fossil fuels.

There have been several estimates of the sink that could be formed by a world-wide attempt to maximize tree planting: Cannell (2003) considered that $2\text{--}5 \text{ Gt C annum}^{-1}$ was ‘theoretically possible’, but $0.2\text{--}1.0 \text{ Gt C annum}^{-1}$ was ‘achievable’. Plantations have so far been established in many parts of the world, including the humid tropics, where the process is much more difficult (and expensive) because of the challenge of weed control.

The idea of carbon forestry supposes that trees will be planted with the primary aim of capturing and storing carbon rather than providing timber or fiber for immediate use. When this becomes the aim, new silvicultural techniques will be applied to minimize the losses at planting and harvesting, and usually the best solution will be some type of continuous cover forestry where clear-felling does not occur.

Reduced Deforestation

In the 1997 Kyoto Protocol, policies were developed to encourage reforestation and afforestation, but deforestation and degradation were excluded as it was considered not practical to measure accurately the rate of these processes with existing satellite surveillance. Later, in 2005, Papua New Guinea led a consortium known as the *Coalition of Rainforest Nations* to consider “the urgent need to take further meaningful action to

reduce emissions from deforestation and forest degradation.” The various steps to achieve forest protection are collectively described as Reduced Emissions from Deforestation and Degradation (REDD). This strategy for countries to unite to protect forests requires substantial funds to be paid from international sources to the countries (and the people) who own and currently use the vulnerable rain forests. The scale of the funding can be estimated as follows: suppose the carbon losses from deforestation are presently 1.2 billion tonnes of carbon per year, as shown in [Figure 1](#). This quantity of carbon on combustion will release some 4.4 billion tonnes of CO₂ into the atmosphere. In the last few years, carbon has been traded at about US \$14 per tonne of CO₂, and so the relevant value (assuming that prices are unaffected by introducing a new element into carbon trading) is 61.5 billion dollars per year, which is a mere 0.083% of the global economy.

Binding international agreement to support REDD was supposed to be reached in 2009, but countries failed to agree on terms. However, a number of international and national agencies and governments have pledged substantial money for specific REDD projects, amounting to billions of dollars.

REDD is sometimes linked to the sustainable management of forest and also enhancement of forest cover, in which case the term REDD+ is applied.

Barriers that have prevented the development of REDD include the problem of achieving consistent satellite remote sensing of deforestation, but since 1997, when this seemed a major issue, a great deal more research has been carried out. The limitations of optical remote sensing are better understood, and radar remote sensing is expected to overcome many of the perceived problems. Another barrier is the issue of weak governance and unstable government in some of the beneficiary countries.

Meanwhile, there has long been widespread recognition that rain forests provide a multiplicity of environmental services. These go far beyond merely carbon capture. Foremost is the realization that more than half of the world’s estimated 10 million species of plants, animals and insects live in the tropical rain forests. Less widely appreciated (less visible) is the role of rain forests in water and soil protection, rainfall generation, climate regulation, and food supplies. It is not surprising that an informal carbon market developed spontaneously in the wake of the Kyoto Protocol, much of it in the forestry sector, and as a result, it is possible for companies and private individuals to purchase certified carbon credits to offset their own emissions, for example associated with air travel. Forest protection projects have been conducted in both temperate and tropical countries ([Jindal et al., 2008](#)), and their successes and failures provide useful lessons for any future regulatory carbon market.

Future of the Carbon Cycle, 100-Year Perspective

The exploitation of fossil fuels is likely to continue as long as easy-to-obtain stocks of oil, gas and coal remain. As an aid to thinking of the future, and managing the carbon cycle over the next century, [Pacala and Socolow \(2004\)](#) introduced the carbon wedge concept ([Figure 6](#)). In this diagram, it is envisaged

that energy demand will continue to increase, but a growing fraction of the requirement will be met by savings made by making energy utilities more efficient, by Carbon Capture and Storage, and by alternative energy sources. These measures cannot be brought in immediately. Some depend on technologies that are already developed, like nuclear energy, and others require much greater investment of research and development before they can be implemented at full scale. Thus, they are shown as a series of wedges. In Pacala and Socolow’s (2004) original IPCC (2005) paper these wedges represent efficient vehicles, reduced use of vehicles, efficient buildings, efficient coal plants, CO₂ capture, replacing coal energy by nuclear energy, wind power, solar power, biomass power, reducing deforestation and soil management. Application of all of these measures (and perhaps more, as several are excluded) might stem the increase of CO₂ to 500±50 ppm and thus limit global warming.

Currently, the scenario of replacement of carbon energy by wedges of efficiency and alternatives seems optimistic. It is likely that CO₂ concentrations and global temperatures will continue to rise, despite the 2009 economic recession, more or less in line with the pessimistic scenarios drawn up by IPCC (2007).

A crucially important question becomes: how will the existing sinks respond to global warming? A number of early modelling investigations suggested that quite small amounts of warming would cause carbon to be lost from the Amazon forests because a rise in temperature tends to increase respiration more than it increases photosynthesis ([Grace et al., 1995](#); [Cox et al., 2000](#)). Increases in temperature are often

Figure 6 The Pacala-Socolow concept of stabilization wedges. In this diagram, business-as-usual would lead to a near-linear increase in CO₂ emissions to the mid-century. Emissions can, however, be stabilized by decarbonizing the energy supply and capturing carbon dioxide before it reaches the atmosphere. In this drawing, seven wedges are used to show how the gradual introduction of remedial measures might allow the business-as-usual energy demand to be satisfied while stabilizing the atmospheric CO₂ concentration.

accompanied by drought, and now we know from observational data that hot dry weather in both temperate and tropical forest is accompanied by substantial failure of the land carbon sink (Ciais *et al.*, 2005; Lewis *et al.*, 2011). Indeed, it has been known for some time that the CO₂ concentration of the atmosphere increases more in El Niño years, when drought prevails in several parts of the world (Heimann and Reichstein, 2008). Most climate models show that in future, we may expect higher variability in the climate, and some of them predict that El Niño will become more frequent and extreme. However, this remains a topic of research.

The strength of the ocean sink may also decrease in response to climate warming (Schuster & Watson, 2007). Failure of both the land and the ocean sink would mean that the atmospheric concentrations of CO₂ would rise much more rapidly in response to increasing emissions, thus leading to a positive feedback and potentially cataclysmic warming.

However, there may be negative feedbacks, as yet unknown, which act to stabilize the world's climate. In the meantime, the Precautionary Principle should be applied and the energy supply should be decarbonized as soon as possible.

Climate Change: Anticipating and Adapting to the Impacts on Terrestrial Species

Joshua J Lawler, Carrie A Schloss, and Ailene K Ettinger, University of Washington, Seattle, WA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Adaptation Actions that ameliorate the impacts of climate change on systems or species or that allow for systems and species to take advantage of climatic changes.

Adaptive management An iterative process of management and monitoring that treats management actions as experiments, the results of which inform changes in management actions.

Assisted colonization The translocation of species outside of their native range to allow them to track changes in climate.

Co-benefits Beneficial outcomes for human or natural systems of adaptation or strategies designed to address one or the other system.

Mitigation Actions designed to reduce the amount that the climate will change. These actions generally involve reducing greenhouse gas emissions and sequestering carbon dioxide (CO₂).

Phenology The timing of ecological events.

Resilience The ability of a system or species to return to its initial condition after perturbation by climate change.

Resistance The ability of a system or species to remain largely unchanged in the face of climate change.

Triage A system of prioritization for making decisions when resources are scarce and the need for responses is widespread.

Introduction

Climate change is poised to significantly alter ecological systems. Recent climatic changes have resulted in clear shifts in species distributions and the timing of ecological events (Parmesan, 2006). Although range shifts and changes in phenology are the two most well documented effects of recent climatic changes, there are a myriad of other ways in which changes in climate have affected and will likely affect terrestrial species. Among other things, climate change has the potential to alter population processes, interspecific interactions, and the impact of diseases and parasites. All of these effects have been documented to some degree.

The magnitude and rate of climatic changes projected for the coming century will provide challenges for many terrestrial species (IPCC, 2007a, b). Addressing these challenges will require some understanding of how species will likely respond to projected changes. There are several tools that can help scientists, managers, and planners anticipate the impacts of climate change on terrestrial species. These tools range from understanding historical patterns and conducting experiments to developing complex simulation models to forecast potential impacts.

An understanding of how species will likely respond to climate change is critical for developing management strategies and policies to maintain populations, protect species, and sustain ecosystem functions in a changing climate. Such approaches are generally referred to as adaptation strategies. The Intergovernmental Panel on Climate Change (2007a) has defined adaptation as “the adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities.” Many adaptation strategies have been proposed for terrestrial ecological systems and specifically for

terrestrial species. The majority of these strategies are broad recommendations or general concepts, but some are more specific actions.

The following sections provide both an overview of some of the impacts of climate change and how they can be anticipated and a review of the adaptation strategies that have been proposed for addressing these impacts.

Anticipating Impacts

There are many potential impacts of climate change on terrestrial species. The following sections concentrate on six types of impacts – impacts on phenology, range shifts, population processes, interspecific interactions, diseases and parasites, and interactions with other, nonclimatic stressors. Each section provides an overview of impacts and approaches for anticipating those impacts.

Phenology

One of the most widely observed ecological effects of climate change is a shift in phenology – the seasonal timing of life history events, such as flowering, egg hatching, migration, and senescence. For centuries, people have been observing phenology for agricultural and religious reasons, as well as simply to record changing seasons. For example, grape harvest dates have been tracked for the past 500 years across Europe (Menzel, 2005) and the appearance of spring cherry blossoms has been recorded since the fifteenth century in Japan (Menzel and Dose, 2005). In general, these and other historical data suggest a shift in the seasonal timing of biological events as temperatures have risen over the past century. Spring and summer events, including frog spawning, bird nesting, and

leaf unfolding, are occurring earlier, and the vegetative growing season has lengthened (Parmesan, 2006; Feehan *et al.*, 2009; Thackeray *et al.*, 2010). These changes have occurred rapidly and have been particularly strong at high latitudes, where warming has been the greatest (Parmesan, 2006; Feehan *et al.*, 2009). From 1976 to 2005, phenology of plants, invertebrates, and vertebrates in terrestrial, marine, and freshwater environments advanced, on average, by 11.7 days (0.38 days per year) (Thackeray *et al.*, 2010).

Although there has been an overall advancement in the timing of biological events, significant variation exists in patterns of phenological shifts across ecosystems, species, trophic levels, and functional groups. Of terrestrial organisms, plants have shown the most rapid rate of change (0.58 days per year from 1976 to 2005), and vertebrates have shown the slowest (0.25 days per year) (Thackeray *et al.*, 2010). These varying rates of change suggest that asynchronies may develop between interacting species, such as predators and their prey or plants and their pollinators. Indeed, asynchronies, or “phenological mismatches,” have already been observed and, in some cases, have resulted in both reductions in individual fitness and declining population sizes (Parmesan, 2006; Forrest and Miller-Rushing, 2010; Miller-Rushing *et al.*, 2010).

By combining historical relationships between phenologies and climate with future climate projections, research efforts have begun to forecast how future changes in climate will affect phenology and the consequences of these potential phenological shifts (Memmott *et al.*, 2010; Ogden *et al.*, 2008a, b; Tobin *et al.*, 2008; Caffarra and Eccel, 2011). These forecasts project continued shifts toward earlier arrival of spring events, particularly at high altitudes (Caffarra and Eccel, 2011). Forecasts suggest that climate-induced phenological shifts can have major impacts on species interactions and communities, even when complete phenological mismatches do not occur (Fabina *et al.*, 2010).

Forecasting future phenological shifts is difficult, because the understanding is based largely on correlative observational studies. In many cases, there is no mechanistic understanding of controls over phenology and the degree to which it is controlled by climate. Genetics and nonclimatic cues such as photoperiod also affect phenology (Forrest and Miller-Rushing, 2010; Valtonen *et al.*, 2011). Furthermore, observational data have been biased toward plants, and the knowledge of trends in other organisms is limited. Even when extensive data and understanding are present, it may be problematic to assume that future trends will follow those in the past. For example, in the Tibetan Plateau, from 1982 to 2006, trends in spring vegetation phenology initially advanced concurrent with warming patterns, but started retreating in the mid-1990s in spite of continued warming (Yu *et al.*, 2010). The authors conclude that warm winter conditions caused a delay in spring phases due to chilling requirements. Species- and site-level variations in the magnitude and direction of phenological responses to changes in temperature highlight the need for further research on climate-induced shifts in phenology. In particular, mechanistic studies that determine the influence of climate on phenology and research on mammals, amphibians, fungi, and other understudied organisms are needed to improve the ability to anticipate future phenological changes.

Range Shifts

Climatic factors broadly determine species distributions, and therefore, climatic changes can cause associated changes in species distributions, or range shifts. Over the past century, both altitudinal and latitudinal range shifts in temperate- and tropical-terrestrial species have accompanied climatic changes (Parmesan and Yohe, 2003; Parmesan, 2006; Walther *et al.*, 2002; Root *et al.*, 2003). As the climate changes, species expand their ranges to occupy previously climatically unsuitable areas (Parmesan, 2006). Conversely, climatic changes may reduce the climatic suitability of species' current distributions, resulting in range contractions through local population extinctions (Parmesan *et al.*, 1999). The combination of range expansions into regions of newly suitable climate and range contractions away from regions of unsuitable climate can result in overall shifts in species ranges (Pearson and Dawson, 2003; Parmesan *et al.*, 1999).

Range shifts have been documented for plants, insects, birds, mammals, amphibians, and reptiles in tropical, temperate, and arctic regions. Overall, the magnitude and direction of these shifts have been consistent with climatic changes and tend to be poleward and/or upward in elevation, with an average shift of 6.1 km poleward or 6.1 m upward per decade (Parmesan and Yohe, 2003). Despite the general trend of upward and poleward range shifts, distributional responses to climate change are largely individualistic, with some species showing no change in their distributions despite warming and others showing shifts inconsistent with climatic changes (Parmesan and Yohe, 2003; Parmesan, 2006). The inconsistent shifts likely reflect the different degrees to which nonclimatic factors influence species distributions (Hellmann *et al.*, 2008b). For example, local-scale patterns, species interactions, habitat requirements, or proximity to source populations may be more important than climatic conditions in determining range shifts and establishment for some species (Elliott, 2011; Matthews *et al.*, 2010; Melles *et al.*, 2011). Many factors that interact with climate change to influence species distributions make projecting climate impacts on species ranges particularly difficult.

Nonetheless, many studies have used predictive models to project the potential effects of climate change on species distributions. Most of these studies have used species distribution models (often referred to as niche models or climate-envelope models in the context of climate change) that relate current climatic patterns to current species distributions and use this relationship along with projections of future climate from general circulation models to project future species distributions (Pearson and Dawson, 2003; Guisan and Zimmermann, 2000). These projections are often consistent with the direction of observed range shifts. Bioclimatic model projections can provide useful approximations of the magnitude and location of climate-induced changes to continental biodiversity. Projections have been made for a wide array of plants and animals in most regions of the world.

Despite widespread use of bioclimatic models, there are many uncertainties associated with the projections they produce. For example, projections from bioclimatic models are sensitive to the uncertainties associated with forecasts of future climate and the type of bioclimatic model employed.

Disparate projections can be summarized using ensembles of different types of species distribution models that incorporate projections from multiple climate models (Buisson *et al.*, 2010). In addition to the uncertainties, bioclimatic models have other limitations. For example, they generally do not incorporate the influence of nonclimatic factors (e.g., species interactions, dispersal potential, or habitat requirements), the potential for species to adapt to new climatic conditions rather than move to regions of suitable climate, and the possibility that species distributions are not at equilibrium with respect to current climatic conditions (Pearson and Dawson, 2003; Yates *et al.*, 2010; Dormann, 2007). Some bioclimatic models have addressed these limitations by incorporating dispersal potential, biotic interactions, or habitat data (Carroll, 2010; Vos *et al.*, 2008; Midgley *et al.*, 2006). Process-based models further incorporate detail by including biological processes parameterized by observations or measured species physiological tolerances and may provide more accurate forecasts of species distributions (Morin *et al.*, 2008; Morin and Thuiller, 2009; La Sorte and Jetz, 2010; Morin and Lechowicz, 2008).

Population Processes

Although projected range shifts provide a coarse view of how species will likely respond to climate change, they do not capture detailed changes that will occur at finer spatial scales. For example, climate change affects population processes such as birth and death rates, individual growth and reproductive capacity, life expectancy, immigration, and emigration. All of these processes affect short- and long-term changes in the size and age-structure of populations and determine whether populations increase, decrease, are able to establish in unoccupied regions, or go extinct. By observing population sizes and demographic parameters through time and by modeling population dynamics using observed vital rates, the authors have gained tremendous insight into climate-sensitive population processes.

Climate change affects population dynamics directly when changes in temperature, precipitation, or other climate factors alter vital rates in a population. Diverse population responses have been observed and forecasted, with some populations increasing due to climate change, others decreasing, and still others remaining essentially stable. Many insect populations, including mosquitoes and some beetles, are expected to increase in a warmer world, often because reproductive success (specifically, hatching and larva survival) is positively correlated with temperature (Morin and Comrie, 2010; Jonsson *et al.*, 2007; Estay *et al.*, 2009). Alternatively, populations of other organisms, such as tree species in western North America and polar bears in the arctic, are expected to decrease because of increased mortality rates associated with climate change (van Mantgem *et al.*, 2009; Molnar *et al.*, 2010). Because, for some species (e.g., many reptiles), the sexes of offspring are determined by temperature, changes in climate are expected to alter sex ratios, which may decrease long-term population viability (Mitchell *et al.*, 2010).

Climate change also indirectly affects population processes through interspecific interactions. Climate-sensitive dynamics in one species may lead to altered population processes of

another species. For example, in alpine areas of Colorado, USA, the growing season has lengthened over the past 30 years, leading to declines in yellow-bellied marmot mortality, which triggered increases in their population sizes (Ozgul *et al.*, 2010).

Within communities and ecosystems, population-level responses to climate change vary greatly between and within species. For example, forecasted temperature increases are expected to cause rising soil temperatures in much of the world, potentially differentially affecting the longevity and dynamics of persistent soil seed banks of plants. In an arid region of Australia, some plant species showed significantly greater levels of germination after exposure to predicted increases in soil temperatures, whereas others experienced dramatic decreases in seed viability (Ooi *et al.*, 2009). Even within a species, population-level responses to climate change may differ. For example, American beaver populations are predicted to expand modestly at their northern range limits as a result of climate change, but population densities are likely to increase more dramatically in the interior portions of the beaver's range (Jarema *et al.*, 2009).

Even small alterations to vital rates due to climate change can have large consequences for population trajectories (McRae *et al.*, 2008). As computing power has increased, the capacity to model the effects of climate change on population dynamics has improved, and in recent years, studies have combined climate forecasts or bioclimate envelope models with population viability analyses and spatially explicit stochastic population models (Ooi *et al.*, 2009; Keith *et al.*, 2008; Mitchell *et al.*, 2010). Such forecasts are data and computationally intensive, but enable one to understand and better prepare for ecological impacts of climate change.

Interspecific Interactions

Climate-change-induced shifts in ranges, phenology, and population dynamics can lead to altered interspecific interactions and the formation of novel communities. Even strongly interacting species, such as specialist pollinators and the plants they pollinate, may have large differences in their physiological tolerances, life history strategies, and dispersal abilities. Differences in sensitivities and adaptive capacities can lead to decoupling of even the strongest relationships. Species' individualistic responses to climate change make forecasting altered species' interactions enormously challenging, and scientists often combine observational or experimental studies with modeling.

Climate change affects species interactions both within and across trophic levels. Effects on plant interactions are the best documented, but recent studies suggest that climate change alters competitive interactions among animals as well and causes shifts in other interspecific relationships across trophic levels. Increasing temperature and carbon dioxide may intensify pathogen infection rates, weaken mutualisms involving plants (e.g., pollination and seed dispersal), and enhance herbivory, particularly by insects (Parmesan, 2006; Tylisanakis *et al.*, 2008; Traill *et al.*, 2010). Studies predict largely negative ramifications for important ecosystem services provided by species interactions, such as natural pest control by consumers

of insects, as well as the potential for increases in species coextinction rates (Traill *et al.*, 2010).

It is challenging to anticipate future effects of climate change on species interactions, but the ability to accomplish this is improving with the development of new forecasting tools and with an expanded knowledge base and data. Bioclimatic models can be fit separately for interacting species to evaluate the likelihood of altered interactions under future climates (e.g., interaction between a monophagous butterfly and its larval host plant) (Schweiger *et al.*, 2008). Bioclimatic models can also be nested, with the output for one species becoming a predictor variable for another species, to incorporate species interactions into projections of range shifts. Including these interactions is generally thought to improve explanatory and predictive power (Preston *et al.*, 2008; Sutherst *et al.*, 2007; Araújo and Luoto, 2007). Mechanistic models that explicitly incorporate species interactions can also be used to forecast range shifts (Ponti *et al.*, 2009), but these models are data intensive. Thus, observational and experimental studies are also needed to improve the understanding of species interactions and effects of climate and carbon dioxide concentrations on these interactions, particularly for mammals, amphibians, fungi, and other understudied organisms.

Diseases and Parasites

Diseases and parasites are specific instances of interspecific interactions that will likely be affected by climate change. The impacts of climate change on terrestrial species (i.e., phenological changes, range shifts, and changes in population processes) also affect parasites, diseases, disease vectors, the susceptibility of hosts, and the interactions between all of these organisms. Therefore, climate change will both directly and indirectly affect the emergence and spread of parasites and disease (Canto *et al.*, 2009). The impacts of climate change on parasites, diseases, vectors, and hosts are individualistic, and interactions between these impacts are complex (Moller, 2010; Luck *et al.*, 2011; Lafferty, 2009; Garrett *et al.*, 2011). However, the frequency of parasite and disease outbreaks will likely increase in a changing climate (Canto *et al.*, 2009; Brooks and Hoberg, 2007). These outbreaks have the potential to negatively impact plants and wildlife, agriculture, and human health (Reid and Gamble, 2009; Luck *et al.*, 2011; Patz *et al.*, 2007; Fussel, 2008; Garrett *et al.*, 2006).

Physiological tolerances to climatic conditions often determine disease and parasite distribution and abundance. Therefore, climate change will directly impact diseases with free-living life stages and diseases that require ectothermic vectors or hosts (Mas-Coma *et al.*, 2009; Patz *et al.*, 2008; Polley and Thompson, 2009). For example, the ability for parasites or disease vectors to overwinter requires a specific range of climatic conditions (Garrett *et al.*, 2006). Also, incubation time and the number of generations per year for some vectors and parasites are sensitive to temperature and humidity, and therefore, outbreaks of diseases and parasites will be impacted by climate change (Patz *et al.*, 2008; Jaramillo *et al.*, 2009). In general, higher precipitation and temperatures correspond with a higher disease transmission rates and

higher diversity of diseases (Lafferty, 2009; Froeschke *et al.*, 2010). However, the responses of parasites and diseases to climatic changes are species specific, and so the resultant impact on hosts may be positive, negative, or neutral (Garrett *et al.*, 2006). For example, for a single host species, multiple parasites responded differently to changes in different climatic variables, resulting in no change to the fitness of the host species (Moller, 2010).

Because of the individualistic responses of parasites, diseases, vectors, and hosts to climate change and the complexity of the interactions of these responses, forecasting the impact of parasites and disease is difficult. Despite these complexities, projections are important to identify regions that are most susceptible to disease emergence or parasite outbreaks to facilitate proactive responses. Process-based models are often used to forecast the response of diseases to climatic changes by modeling climatic tolerances for survival, transmission, and reproduction (Rosenthal, 2009). For example, plague levels in black-tailed prairie dogs are forecasted to decrease due to inhibited transmission from higher temperatures (Snall *et al.*, 2009). Likewise, a simulation of host–parasite dynamics forecasts reduced transmission rates from stochastic events in regions of host expansion (Phillips *et al.*, 2010).

Phenological changes will also impact disease and parasite transmission and abundance. For example, increases in the length of flying seasons of disease vectors and parasites may increase disease transmission and the spread of the disease (Canto *et al.*, 2009). Conversely, phenological changes may also reduce the impact of parasites and disease by causing mismatches with hosts. Process-based models can also forecast phenological changes and the effects of those changes on population dynamics and pathogen–host dynamics (Ogden *et al.*, 2008a).

As climates change, new regions may become climatically suitable for a parasite, disease, or disease vector. Diseases and parasites may expand into these previously unsuitable, uninhabited regions. Species distribution models have been used to project range shifts for diseases, parasites, vectors, and hosts. For example, species distribution models for a tick, *Rhipicephalus appendiculatus*, and several host species forecasted overall range reductions for the tick and hosts, but an increase in tick–host assemblages in certain regions (Olwoch *et al.*, 2009). As for all species, nonclimatic factors such as dispersal limitations, land use, and interspecific interactions may limit climate-induced range expansions (Lafferty, 2009). However, disease and parasite distributions may be even more sensitive to nonclimatic distributional determinants because of their complex interactions with vectors and hosts. Therefore, forecasts from species distribution models may not be as effective as process-based models for anticipating the impacts of climate change on parasites and disease. For parasites and diseases, in particular, host availability may influence range expansion (Lafferty, 2009; Rosenthal, 2009). For example, if parasite or disease distributions are limited by host availability, distributional shifts of host species may correspondingly cause shifts in disease and parasite distributions. Also, climate change increases the potential for host switching, which may cause disease outbreaks in previously unaffected species that may be difficult to anticipate (Brooks and Hoberg, 2007). Pest and disease control may also have a large influence

on the distribution of a disease (Rosenthal, 2009). Diseases that affect humans in particular are sensitive to nonclimatic distributional determinants due to public health programs that are often influenced by socioeconomic distributions (Rosenthal, 2009). The extensive influence of nonclimatic factors on the distributions of diseases and parasites may overwhelm the impact of climate change, making impacts somewhat difficult to forecast.

Interactions with Other Stressors

Climate change will not affect species in a vacuum, but instead will interact with other factors that currently affect population dynamics or species distributions. These other factors include, but are not limited to, invasive species, land-use change, disturbance, and human responses to climate change.

Invasive Species

Invasive species are also experiencing changes in phenology and distributions, which may exacerbate the threats of climate change to native species. Climatic changes are likely to result in increases in invasive species' survival, abundance, and range expansions. Experiments and field observations provide evidence of the tendency for invasive species to outcompete native species in a changing climate (Verlinden and Nijs, 2010; Willis *et al.*, 2010). First, invasive species have a higher propensity than native species to adjust their phenology in accordance with climatic changes. The more adaptable phenologies of invasive species facilitate community invasions and also lead to increases in the abundance of invasive species (Willis *et al.*, 2010). Moreover, characteristics common to invasive species such as high dispersal abilities, high growth rates, short generation times, and broad climatic tolerances facilitate rapid range expansion in accordance with the rapid changes in climatic conditions (Schweiger *et al.*, 2010; Hellmann *et al.*, 2008a). Bioclimatic models can forecast the extent of a species' invasive potential in a changing climate by projecting the distribution of suitable climate for the invader. Forecasts of potential invasions from climate-change-induced expansions comprise most of the recent research on the interaction of invasive species and climate change. Generally, these models predict expansions of the invaders' ranges (Bradley *et al.*, 2010; Jarnevich and Stohlgren, 2009). However, in regions where they anticipate contractions, forecasts can provide useful guidance for restoration of sites that are no longer suitable for an existing invader (Bradley and Wilcove, 2009). Incorporating invasive ranges into bioclimatic models may also be useful for improving the forecasts of species distributions by more accurately approximating fundamental climatic niches (Beaumont *et al.*, 2009).

Climate-change-induced range shifts of native species may challenge the traditional definitions of nonnative and invasive species as ranges expand beyond species' historical distributions. Previously noninvasive species have the potential to become invasive in a new region without the biological controls provided by interspecies interactions present in the previous community (Hellmann *et al.*, 2008a). Bioclimatic models do not predict these changes in fitness or species

interactions and so may underestimate the potential for ecosystem invasions from previously noninvasive species.

Land-Use Change

Changes in land use, and the corresponding habitat destruction, are currently the greatest threats to biodiversity (Hoffmann *et al.*, 2010; Dawson *et al.*, 2011). The interaction between climate change and land use may exacerbate the impacts of both stressors to flora and fauna. Land use may limit species' range expansions by inhibiting population establishment or impeding movement to climatically suitable regions (Feeley and Silman, 2010). This inability to realize range expansions may result in reductions in range size and decreases in species richness. Climate projections and associated response models can be used to assess these potential interactions and compounding impacts. For example, a process-based dynamic global ecosystem model forecasted a shift in the climatic conditions that are associated with high species richness in northern South America from less impacted to highly modified landscapes that cannot support as many species, resulting in a reduction in overall richness (Higgins, 2007).

Not only will land use inhibit range expansions, but it may also cause distributional shifts (Hockey *et al.*, 2011; Gehrig-Fasel *et al.*, 2007). These range shifts either augment climate-induced shifts or result in shifts inconsistent with the direction of climatic changes. Climate projections can also be coupled with land-use projections to anticipate species responses to these combined threats. For example, in Switzerland, the broad-scale changes forecasted in the distributions of nonvascular plants were attributed to climate change, whereas more local scale changes were attributed to land-use change (Nobis *et al.*, 2009). An individual-based population model anticipated that projected land-use changes will have a larger impact on habitat quality than climate change, but that climate change is still likely to impact the population dynamics of two bird species in the Willamette National Forest (McRae *et al.*, 2008).

Land use may also act as an additional driver of phenological advancement and may further exacerbate the impacts associated with phenological changes (Neil *et al.*, 2010). For example, urbanization may create warmer microclimates resulting in further advancement of phenology (Neil *et al.*, 2010). Together, land-use change and climate change also lead to increases in the prevalence of invasive species and diseases, further challenging floral and faunal communities (Crowl *et al.*, 2008; Patz *et al.*, 2008). Modeling approaches that anticipate impacts will be important for proactive management to address these potential compounding threats.

Disturbance

Climate change has the potential to alter the frequency and severity of disturbances, such as fire, resulting changes in ecosystem structure and/or function. Climate change has already altered fire regimes through increases in fire severity and area burned, and these impacts are projected to increase in the future (Littell *et al.*, 2009; Marlon *et al.*, 2009; Nitschke and Innes, 2008; Podur and Wotton, 2010). Increases in fire severity alter community composition through the loss of nonvascular plants, shrubs, and drought-sensitive species and

the rapid species establishment that succeeds severe burns (Colombaroli *et al.*, 2007; Bernhardt *et al.*, 2011). Climatic changes may also increase the fire susceptibility of communities that have historically lacked fire regimes. Ignition in these newly susceptible regions will further alter community composition (Malhi *et al.*, 2009).

Many studies have forecasted changes in fire severity and the area burned. These projections are significantly different from historical time-series simulations (Keane *et al.*, 2008) and generally include longer fire seasons, increases in fire severity, shifts toward full crown fires, and increases in the area burned (Podur and Wotton, 2010; Nitschke and Innes, 2008; Malevsky-Malevich *et al.*, 2008). However, far fewer studies forecast the impacts of these fire-regime changes on species and community composition.

The Human Response to Changes in Ecosystem Services

Through impacts on species, communities, and ecosystems, climate change will alter the goods and services provided by Earth's ecosystems. Ecosystem services include a wide array of benefits that people derive from ecosystems including provisioning, regulating, cultural, and supporting services. Provisioning services are those that deliver products that humans use (e.g., water, food, fiber for clothes, and shelter). Regulating services are those that control the states and rates of physical and biotic systems and processes in ways that are beneficial to humans (e.g., the reduction of storm-surge damage by mangrove forests, flood control by riparian systems, and carbon sequestration and storage by plants). Cultural services increase societal and spiritual well-being (e.g., the provision of recreational amenities, spiritual experiences, esthetics, and human health). Supporting services are those that assist in the provision of all other services such as nutrient and water cycling, pollination, and nitrogen fixation.

There are many ways in which climate change will alter the quantity or quality of the four different types of services. For example, shifts in species distributions have the potential to directly affect the provision of many food resources, particularly for human communities that rely on wild-caught foods. Climate change will also affect regulating services such as the ability to grow specific crops in particular locations (Lobell and Asner, 2003; Lobell and Field, 2007; Battisti and Naylor, 2009) and the quantity and quality of water for drinking and irrigation (Vörösmarty *et al.*, 2000). Changes in phenology, pollinator communities, soil microbial communities, the distribution of pest and pathogens, and invasive species all have the potential to alter supporting services for food production. Changes in microbial communities also have the potential to alter nutrient cycling, water purification, and timber and other fiber production.

Understanding how ecosystems services will change in the future and how humans will respond will be a critical step in developing adaptation strategies for species and systems. Crop failure, water shortages, and sea-level rise will force human migrations and likely result in conflicts between humans and terrestrial species, particularly in developing countries. These migrations and conflicts will further displace some terrestrial species and potentially provide opportunities for others. Shifts in the modes of energy production also have the potential to negatively impact species as solar arrays, wind farms, and

biomass production replace oil and gas extraction. Efforts to increase carbon sequestration, however, have the potential to benefit species depending on the approach taken.

Studies have begun to examine the potential effects of climate change on specific ecosystem services; however, few studies have attempted to evaluate the impacts of climate change on suites of ecosystem services (Hayhoe *et al.*, 2004; Metzger *et al.*, 2008; Schröter *et al.*, 2005; Alcamo *et al.*, 2005). Many of the methods that are applicable to projecting changes in ecosystem services are those that can be used to assess the potential effects of climate change on species and ecological systems. In addition to these approaches, methods for quantifying the services themselves will also be needed. Many models have been devised for evaluating ecosystem services (Kareiva *et al.*, 2011), and some of these have been coupled with climate projections to investigate the impacts of climate change on these services (Lawler *et al.*, 2011). Estimating the human response to these changes in services requires going beyond the ecosystem service model projections and forecasting human migrations, land-use changes, water use, and other human actions. These predictions can, like the projections of ecological responses, be derived from predictive models or be based on historic patterns or the results of surveys and other socioeconomic studies.

Adaptation

There are two types of actions that humans can take to reduce the impacts of climate change. Mitigation actions reduce the amount that the climate will change. Such actions include approaches for reducing greenhouse gas emissions and sequestering atmospheric carbon dioxide. Adaptation actions are those that reduce the impact of a given magnitude of climate change and include approaches such as protecting more land, restoring riparian areas to reduce stream temperatures, and moving species to more suitable climates. There are several general concepts that have guided the development of adaptation strategies. These are discussed in the section, General Concepts and Principles, below. This section is followed by sections describing specific Adaptation Strategies, Challenges to Adaptation, and the co-benefits of adaptation (in Multidimensional Strategies).

General Concepts and Principles

Many of the commonly recommended climate-change adaptation strategies for species and ecological systems tend to be general concepts for altering the way species and systems are managed. These concepts include assessing vulnerability, managing for resistance and resilience, planning at broader spatial scales, increasing cooperation and coordination in planning and management, and employing adaptive management and triage when necessary. These general concepts are discussed briefly.

Vulnerability

Climate-change adaptation is deeply tied to the concept of vulnerability – the extent to which a species, an ecosystem, or

an area is likely to be harmed as a result of climate change and associated stresses (Brooke, 2008). Vulnerability can be defined as having three components: sensitivity, exposure, and adaptive capacity (Dawson *et al.*, 2011). Sensitivity refers to innate characteristics of an organism or ecosystem (e.g., tolerance to changes in temperature) that predispose it to being more or less susceptible to climate change. Exposure refers to the amount of change either in climate or in climate-driven factors that a species or system will face. Adaptive capacity is a measure of the ability of a species or system to respond in a way that reduces the impacts of, or to takes advantage of, climate change. Vulnerability assessments inform adaptation planning by documenting aspects of all three of these components of vulnerability and using them to identify which species or systems will be affected by projected climate changes and the causes of those impacts Glick *et al.* (2011).

Resistance, Resilience, and Fostering Change

There are three general approaches to managing systems in the face of climate change. One can attempt to manage a system to resist change, to make it resilient to climate change, or to foster change to a new state. Much discussion has focused on managing for resilience. Resilience can be defined in several ways. Here, resilience is defined as the ability of a species or system to return to its current state following a perturbation (e.g., Holling, 1973). Systems that are resilient to climate change will be able to maintain ecosystem functions and processes and avoid a transition to a new state as climates change. Managing for resilience is an attractive concept, because, if successful, it allows continued delivery of ecosystem services and, possibly, the persistence of plant and animal populations.

Many of the other general concepts as well as most of the more specific adaptation strategies focus on increasing resilience. For example, reducing other (nonclimatic) threats, increasing genetic diversity, and restoring riparian vegetation are all approaches that will likely increase the resilience of a species or system in a given place. Removing barriers to inland migration of coastal species is also a potential strategy for increasing the resilience of a species, albeit by increasing the adaptive capacity of species to address change.

Given the magnitude of change that is projected for the coming century, it may be impossible to foster resilience in many systems. Managing these systems may require promoting change to a new state. Promoting change in human-dominated systems will likely be more straightforward (e.g., planting new crops) than doing so in more natural systems. Strategies for fostering change include assisted colonization (see below), shifting management efforts from one species to another and more specifically promoting newly arriving species. The outcomes of these more aggressive and forward-looking strategies will be more uncertain and their implementation (as is already evident with assisted colonization, Ricciardi and Simberloff, 2009) will be more controversial.

Spatial and temporal scales

Climate change is a global phenomenon that will result in long-term changes in ecological systems. The spatial and temporal scales of the changes one is likely to see far exceed the scale of the traditional 1 m² ecological sample plot and the

time-span of an ecological study. More importantly, these changes exceed the spatial and temporal scales over which most planning and management occur. Managing for species and systems in a changing climate will require taking a broader spatial and temporal perspective (Welch, 2005; CCSP, 2008). Developing climate-change adaptation strategies for species will require planning at regional and, perhaps in some instances, continental scales (Hannah, 2010). Because ecological systems will be undergoing relatively rapid changes for the foreseeable future, managers will have to manage for moving targets. The whole concept of “restoration” must be reconsidered (Harris *et al.*, 2006). Returning ecosystems to a previous state (e.g., before human settlement) with a complement of species that were historically native to the site might be counterproductive in a changing climate.

Similarly, the time frame for planning and management actions will, in many cases, need to shift to address climate change. Planning horizons have traditionally been relatively short – for example, 3- to 5-year plans. Planning in such small increments is likely to result in short-sighted management strategies that are incapable of addressing climate change. Managers and scientists need to strike a balance in terms of the temporal and spatial scales over which climate impacts are projected and the scales at which strategies and plans are developed. Many of the ecological climate-impact forecasts are for periods of 50–100 years in the future. Although these projections will be useful for developing management strategies, managers will also need 10- and 20-year projections.

Cooperation and Coordination

Given the broad spatial scales that will need to be considered to address climate change, managers, planners, and policy makers will need to work together and to coordinate efforts across jurisdictions and traditional management units (Kariva *et al.*, 2008). This will mean developing regional instead of local efforts in which strategies are designed to reach across state, province, or country borders. It will mean collaboration across different governmental agencies that are currently focused on specific systems (atmospheric, marine, freshwater, and terrestrial). It will also mean increasing cooperation among different types of groups such as nongovernmental organizations, local and regional governments, citizen groups, and industry. The US Climate Change Science Program (CCSP) is one such organization that reaches across federal agencies. Other regional and national efforts have been put in place in other parts of the world, but such efforts will need to be increased to address climate change.

Managing for Process Over Composition

Because changes in climate will drive species range shifts resulting in new communities, it will be exceedingly difficult to manage for specific assemblages of species. Many have suggested that such changes will necessitate a shift from managing for species and communities to managing for ecosystem processes and shifting baselines (Harris *et al.*, 2006; Heller and Zavaleta, 2009; Hobbs *et al.*, 2009). In many systems, managing for ecosystem function may mean taking a forward-looking approach in which new species are planted or introduced into a system. As discussed below in the context of assisted colonization, these more manipulative approaches

that tend toward engineering ecosystems and moving species have raised significant concerns and debates about the unintended consequences of such actions.

Triage

Many species and systems will be highly vulnerable to climate change. Given the relative scarcity of funds for conservation, it will be impossible to address the needs of all species. Thus, conservation planners and managers will have to make difficult decisions about how to allocate limited funds. They will likely have to choose which populations and species to try to save and which to let go extinct. Triage is one approach to making such difficult prioritizations.

Triage is a medical ranking system developed for the treatment of patients in emergency situations. Traditionally, the system has had four levels based on the severity of the injuries and the likelihood that the patient will survive. The levels are generally deceased or expectant, critical, severe, and minor. A similar system can be applied to species or populations at risk of extinction in the face of climate change (Lawler, 2009). In such a system, some species would be classified as likely to experience such large changes that management actions will do little to prevent their decline or loss. Other species would be deemed as critically threatened by climate change, but their decline or extinction could be prevented by immediate and intense management efforts. A third class of species would be threatened by climate change but would not be at risk of extinction in the short term, and thus management effort could wait. A final class of species would face relatively minor threats from climate change and could be monitored over time and addressed later if necessary. Although there are both ecological and ethical considerations that make triage unpopular (Kareiva and Levin, 2003), such a system will undoubtedly become necessary as climates change and ecological systems respond.

Adaptive Management

Adaptive management is an iterative process of management and monitoring in which management actions are treated as experiments (Holling, 1978; Walters and Hilborn, 1978). The outcomes of these experiments are used to inform the next round of management actions, which are again treated as experiments. Adaptive management was conceived of for managing uncertain systems, making it potentially a highly useful approach to deal with climate change (Arvai *et al.*, 2006). To address climate change, adaptive management approaches will have four basic steps that will be iteratively repeated (Kareiva *et al.*, 2008). The first step will involve assessing the potential impacts of climate change on the system in question. In the second step, management actions, in the form of experiments with testable hypotheses or predictions, will be designed to address one or more of these potential impacts. The third step involves monitoring the system for climatic changes and system responses. Finally, the results of the monitoring can be used to evaluate the effectiveness of the management actions and to redesign them as necessary before the four steps are repeated.

Adaptation Strategies

Climate-change adaptation strategies are practices and adjustments that enhance resilience and/or reduce vulnerability to changes in climate (IPCC, 2007a). These strategies have been implemented across the globe on a limited but increasing basis, in both developed (Krysanova *et al.*, 2010; Olesen *et al.*, 2011; Tompkins *et al.*, 2010; Wheeler, 2008) and developing countries (Krysanova *et al.*, 2010; Mertz *et al.*, 2009; Ziervogel and Zermoglio, 2009). The following section describes some of the adaptation strategies that have been proposed for protecting terrestrial species in a changing climate.

Protected Areas: Reserve Selection and Design

By providing species with refuge from many threats, protected areas have the potential to increase the resilience of species and populations to climate change (Hunter *et al.*, 2010). However, climate change brings into question the ability of current protected lands to provide for the biodiversity of the future. Typically, reserve boundaries are static and reserve networks are designed based on current biodiversity. As species' ranges shift with a changing climate, some species may lose protection as their ranges shift out of reserve boundaries, whereas others may move into reserves (Peters and Darling, 1985). Reserves across the globe are anticipated to experience changes in biodiversity composition, and several species may lose protection entirely from the current reserve network (Araújo *et al.*, 2004; Hole *et al.*, 2009). One adaptation response that aims to provide protection for anticipated climate-induced changes in species distributions has been to augment the reserve network by adding reserves to increase the total area protected across a landscape.

Several general rules of thumb have been proposed for addressing climate change in the reserve selection (i.e., the placement of new reserves) and reserve design (i.e., the size and shape of reserves) processes. Most simply, many have suggested increasing the total area protected and increasing the size of existing reserves. All else being equal, larger reserves will be more likely to maintain populations of species as climates change by providing the space to facilitate within-reserve range shifts. Thus, designating larger reserves or designating buffer zones around reserves may help to protect more species for longer periods of time in a changing climate (Peters and Darling, 1985). Similarly, reserves that span strong environmental gradients will also provide more opportunities for within-reserve range shifts by providing future niches at different altitudes as the climate changes. Strategies for the placement of new reserves include placing reserves at the elevational or poleward range limit of key species (Peters and Darling, 1985), at major transitions between vegetation formations (Halpin, 1997) or at the core of species environmental distributions (Araújo *et al.*, 2004). Yet another simple suggestion involves increasing the redundancy in the reserve system. Protecting the same species in multiple places provides multiple opportunities for the species to weather or adapt to climate change.

Others have suggested more sophisticated methods for identifying the best places for new protected areas to address climate change. For example, projected shifts in species distributions can be used to identify areas that are likely to protect

species today as well as into the future under multiple climate-change scenarios (Hannah *et al.*, 2007; Vos *et al.*, 2008). The increase in specificity potentially makes this approach more effective for the targeted species; however, it incorporates higher levels of uncertainty inherent in forecasting future climatic changes and the biotic responses to those changes. For example, the most-often-applied approach for forecasting species range shifts, species distribution or niche modeling, is better suited to describe general patterns and trends in range shifts than to identify particular locations for protecting specific species in the future (Pearson and Dawson, 2003).

Another approach to locate reserves to address climate change involves selecting areas that protect the underlying environmental gradients that largely determine patterns of biodiversity at broader scales, but that will likely remain stable as the climate changes. It has been argued that protecting these underlying gradients essentially protects the stage on which biodiversity will play out as climates change. Some proposed strategies based on abiotic features focus on selecting sites that span elevational gradients or that represent heterogeneity in soils (Peters and Darling, 1985). Other have stressed geologic variability in a reserve network (Anderson and Ferree, 2010), preserving a range of current climatic conditions – with the assumption that future climates may change, but that many climatic gradients will be preserved (Pyke and Fischer, 2005) – and conserving the regional diversity of land facets, or unique combinations of abiotic conditions (i.e., topographic and edaphic features) (Beier and Brost, 2010). These strategies seek to maintain the elements of the landscape that are responsible for the distribution of regional biodiversity, may be more effective due to more specificity in reserve placement, and are robust to the uncertainties of forecasts.

Other abiotic-based strategies target climate conditions by placing reserves in regions projected to be climate refugia. Planners refer to climate refugia both as areas that are projected to experience minimal climatic changes and as areas projected to have cooler microclimates (Hansen *et al.*, 2010; Shoo *et al.*, 2011; Saxon *et al.*, 2005). The former aims to reduce the potential changes in species composition of new reserves so that these reserves will be more effective over a longer period of time for currently protected species. The latter aims to reduce the distance necessary for distributional shifts by locally protecting cooler microclimates. Locally cooler microclimates may occur at slightly higher elevations or be in areas with more vegetative cover or potential for vegetative cover. Although these strategies may depend on uncertain climate projections, they avoid the compounding uncertainty of using climate projections to forecast biotic responses and still incorporate specificity into the planning process.

Connectivity

Range shifts have occurred in the past as species have responded to historical changes in climate. However, during these periods of historical climate change, species movements were not hindered by anthropogenic barriers. Fragmentation of habitat, roads, and other barriers can inhibit species movement or survival in regions of or between newly suitable climates. Not surprisingly, increasing landscape connectivity is the most commonly recommended adaptation

approach for addressing climate impacts on biodiversity (Heller and Zavaleta, 2009).

Until recently, suggested strategies for improving connectivity to address climate change have been somewhat general – for example, placing new reserves between existing reserves, creating a system of stepping stone reserves, or adding reserves in proximity to existing reserves. Recently, studies have highlighted more sophisticated approaches to connecting landscapes to address climate change. One such approach uses climate projections to orient corridors and expand existing reserves in the direction of anticipated climatic changes (Ackerly *et al.*, 2010). Other approaches involve using projected shifts in species distributions to identify potential routes that species would need to take to move from currently suitable climates to places where climates will likely be suitable in the future (Williams *et al.*, 2005; Rose and Burton, 2009). Beier and Brost (2010) recommend using abiotic elements or land facets (described above) to define corridors. Similar to the multiple reserve placement approaches, these connectivity approaches vary in the level of uncertainty in the data, models, and model projections that they draw upon.

Although it will be important to identify potential movement corridors, increasing the permeability of the landscape in general will also be critical (Franklin and Lindenmayer, 2009). It may be possible to manage lands to facilitate species' movements in response to climate change. For example, selective harvest or retention cuts, tree planting, and rotational grazing may provide habitat to facilitate range expansions (Manning *et al.*, 2009; Kohm and Franklin, 1997). It is possible to prioritize areas for these incentives and management actions using approaches similar to those discussed above for the placement of reserves or corridors.

Species- and Place-Specific Approaches

The adaptation approaches discussed above tend to be general concepts or broad-scale actions (reserve selection and promotion of landscape connectivity). Despite the fact that climate change is a global issue and landscape-level actions are therefore necessary, species- and place-specific approaches will also likely be critical components of climate-change adaptation. Species-specific adaptation strategies aimed at preventing extinction of a particular organism may be appropriate for threatened and endangered species for which legal frameworks, such as the US Endangered Species Act and the International Union for Conservation of Nature (IUCN) Red List, may require species-specific protection and for organisms of economic importance to humans. Place-based approaches, such as efforts focused on a particular park or preserve or within a particular city, are important because adaptation strategies are likely to be implemented at local scales, by the private and public land-owners and managers. Proactive management can address the vulnerability of an area or a species by reducing exposure through the manipulation of microclimates, by reducing sensitivity, and by increasing adaptive capacity.

There are several ways in which the degree of local exposure to climate change can be altered. For example, species-based approaches may include supplemental watering of key plant species in drought years (e.g., Pavlik *et al.*, 2002) and altering microclimates of artificial nest boxes for rare

birds by painting boxes white or locating them on north-exposed slopes (Cattray *et al.*, 2011). Place-based approaches can rely on microclimatic variations that provide refugia from large-scale changes in climate (Mosblech *et al.*, 2011). Place-based approaches to reduce exposure may therefore include protection of these natural refugia, as well as planting trees and other vegetation to provide shade and reduce temperatures (Wilby *et al.*, 1998; Wilby and Perry, 2006). These relatively fine scale adaptation actions are often successful, at least in the short term, but may become increasingly expensive, time consuming, and impractical as climate-change progresses.

Adaptation strategies can also address the vulnerability of an area or a species by reducing sensitivity to the effects of climate change. Diverse systems are generally less sensitive to disturbances (Kareiva *et al.*, 2008; Fargione and Tilman, 2005; Schindler *et al.*, 2010). This pattern is true for genetic diversity within a population of a single species (Schindler *et al.*, 2010), as well as for species richness at the ecosystem level (Chapin *et al.*, 2000). Thus, promoting and protecting diversity at multiple levels, from within a species or a population to across different species and functional groups in an ecosystem, is an important adaptation strategy (Glick *et al.*, 2009).

Adaptation strategies can address vulnerability of an area or a species by reducing sensitivity to climate change or by strengthening its adaptive capacity to respond to the effects of climate change. Other stressors, such as land use, invasive species, pathogens, fragmentation, and pollutants, interact with climate change to further harm species and natural systems (Schweiger *et al.*, 2010; Walther, 2010). Reducing these other stressors can increase adaptive capacity and decrease sensitivity to climate change (Glick *et al.*, 2009). Species-specific approaches include reducing harvest levels of focal organisms, limiting their exposure to pollutants and pathogens, reducing habitat loss, and improving connectivity between populations through corridors (Heller and Zavaleta, 2009; Glick *et al.*, 2009). Worldwide conservation efforts have already reduced species' extinctions, particularly by mitigating threats from invasive species on birds and mammals, but efforts need to be augmented in order to abate many substantial threats to global diversity (Hoffmann *et al.*, 2010).

Assisted colonization – the translocation of species outside their native range to facilitate movement in response to climate change – is another strategy for increasing the adaptive capacity of a species. Assisted colonization may be most appropriate in cases in which current species' ranges become inhospitable with climate change and connectivity to suitable regions is severely limited. This approach is controversial because of the potential for negative, ecological, evolutionary, and economic impacts, as well as ethical concerns (Ricciardi and Simberloff, 2009; Sax *et al.*, 2009). Some potentially less controversial strategies include planting climate-resistant species or ecotypes (Glick *et al.*, 2009) and establishing “neo-native forests” in restoration efforts, that is, planting species where they were in the past, but are not found currently (Millar *et al.*, 2007). Many current restoration and forestry practices adhere to strict rules about using only “local” species and ecotypes. To prepare for climate change, one may need to broaden the genetic and species diversity used in restoration and forestry (Glick *et al.*, 2009). In some cases,

even aggressive strategies such as assisted colonization may fail as climate change and other stresses threaten the existence of rare species. These extreme cases will require *ex situ* conservation strategies, including seed banking and captive breeding to ensure the long-term survival of the species.

Protected areas, corridors for movement, and assisted colonization may all help species track changes in climate. However, given the magnitude of projected changes, these measures may be insufficient. It may be necessary to implement policies that facilitate species movements. Such policies may prohibit the destruction of habitat or removal of species in places through which those particular species will likely need to move in response to climate change (Kostyack *et al.*, 2011).

Challenges to Developing Successful Adaptation Strategies

There are several challenges to adaptation planning and implementation. One of the most frequently mentioned challenges to developing climate-change adaptation strategies is the lack of certainty about future climatic conditions. Although climate-change projections and projected climate impacts are necessarily uncertain, some projections are less uncertain than others and many projections can be used to inform the development of adaptation strategies. In general, projected changes in temperature are less uncertain than projected changes in precipitation and projections for the near-term are less uncertain than projections for the more distant future (IPCC, 2007b). Projected climate impacts on terrestrial species will necessarily be more uncertain than climate-change projections as they generally incorporate the uncertainties of climate models and the additional uncertainties about how species or habitats will respond to climate change and/or the uncertainty associated with the modeling approaches used to forecast those responses (Thuiller, 2004).

A second, often-cited challenge to developing adaptation strategies is the lack of projected climatic changes at a spatial resolution that is meaningful for management. The general circulation models that have been used to project changes in climate have, to date, generated projections at scales of degrees of latitude and longitude (IPCC, 2007b). These projections can be downscaled to finer resolutions; however, there are uncertainties associated with downscaling process (Dettinger, 2005; Wilby *et al.*, 1998). Despite the additional uncertainties, downscaled projections are important for understanding how climatic changes may manifest at finer scales. Downscaled data sets are currently available for many regions of the globe, and tools have been developed that make those data sets readily accessible (Girvetz *et al.*, 2009).

A third limitation to developing adaptation strategies is the general lack of information on species-specific responses to climate. Responses to interacting climate variables vary greatly across and within species, and for many terrestrial plants and animals, the relationship between climate variables and performance (i.e., growth, survival, and reproduction) is unknown (Parmesan, 2006). Climate-change effects on species are further complicated by their interactions with biotic factors, such as competition, predation, mutualisms, and other stressors, such as land use, invasive species, pathogens, and pollutants (Schweiger *et al.*, 2010; Walther, 2010). Thus,

for many species, an important first step for climate-change adaption is simply to improve the understanding of responses to climate change, including physiological, behavioral, and demographic responses (Heller and Zavaleta, 2009)

Planning can be difficult in the face of these uncertainties, and currently implemented adaptation strategies are limited in scope and are insufficient to fully address climate-change impacts (Wheeler, 2008; Reyer *et al.*, 2009). One of the primary concerns expressed by land and resource managers is a lack of “downscaled” studies on which to base their decisions, in terms of both climate projections and species responses

(Glick *et al.*, 2009). However, there have been significant advances in model development at regional scales. As one’s knowledge base and expertise grow, a key challenge is to improve communication and cooperation across the many groups and individuals involved in developing climate-change adaptation strategies. Species- and place-specific approaches are practical, because of existing legal, ownership, and management frameworks. Nonetheless, these approaches will be far more effective if there is substantial cooperation and communication within and between groups implementing climate-change adaptation strategies.

Table 1 Example approaches for anticipating and adapting to climate impacts on terrestrial species

Impacts	Anticipating impacts	Adaptation strategies
Phenology Shift in grape flowering and ripening times in montane Australia (Caffarra and Eccel, 2011)	● Project changes in temperature and precipitation ● Apply phenological models of budburst, flowering, and fruit ripening	● Alter grape varieties grown ● Focus on high elevation areas, where climate may become more suitable
Range shifts Shift in the distribution of wolverine in the US	● Project changes in snowpack ● Apply species distribution models ● Map historical ranges and climatic conditions	● Enhance connectivity both northward in latitude and upward in elevation
Population processes Shift to male-biased sex ratios of tuatara reptiles in New Zealand (Mitchell <i>et al.</i> , 2010)	● Conduct population viability analysis under different sex ratios	● Use <i>ex situ</i> techniques to increase females ● Translocate populations to cooler environments or sites with more microclimate complexity
Interspecific interactions Spatial mismatch of a monophagous butterfly (<i>Boloria titania</i>) and its larval host plant (<i>Polygonum bistorta</i>) (Schweiger <i>et al.</i> , 2008)	● Project changes in monthly temperature ● Apply species distribution models for two interacting species ● Map future ranges of two species	● Increase likelihood of plant dispersal by enhancing connectivity between habitat patches ● Facilitate migration of host plant through habitat restoration or planting efforts
Diseases and parasites Change in the prevalence of East Coast Fever (ECF) in sub-Saharan Africa	● Project changes in distribution of a tick and 10 of its host species ● Assess the probability of occurrences of tick–host assemblages ● Apply dilution effect model to determine potential ECF transmission	● Regulate cattle movement to reduce interaction between cattle and wild host species
Interactions with other stressors Impact of multiple stressors on two bird species with varying habitat requirements	● Develop spatially explicit individual-based models ● Apply projected changes in land use ● Apply projected changes in climate	● Evaluate and implement management strategies that increase population viability

Multidimensional Strategies (Co-benefits)

Climate change will have profound effects on many human populations (IPCC, 2007a). These effects include water shortages, crop reductions, and failures resulting in malnutrition, displacement due to sea-level rise, emerging diseases, and armed conflict (Costello *et al.*, 2009). Humans will develop adaptation strategies to reduce these impacts. Dams will be built to store water; more water will be extracted from streams and rivers for agriculture, drinking, and manufacturing; new areas will be cultivated; migrations will occur and settled areas will expand; and wetlands will be drained and pesticides applied to reduce crop pests and disease vectors. Many of these adaptation strategies will have negative consequences for non-human terrestrial species. Conversely, some of these strategies can be designed to benefit nonhuman terrestrial species.

Co-benefits can be defined as the positive effects that an adaptation strategy designed to address a specific human need has on nonhuman species, communities, or ecosystems, or conversely the positive effects on human well-being of adaptation strategies designed to help nonhuman species and systems adapt to climate change. Co-benefits have largely been described for mitigation strategies that, in addition to reducing greenhouse gas emissions, benefit human health (Haines *et al.*, 2007; Jack and Kinney, 2010). Such co-benefits of adaptation strategies have not been as well documented, but these win-win outcomes will likely arise in many instances.

There are clear co-benefits for human health and well-being that are likely to result from adaptation strategies that restore coastal habitats, riparian areas, and flood plains. Removing sea walls, restoring mangrove forests and dune systems, and protecting barrier beaches are all adaptation strategies that will increase the resilience of coastal plant and animal communities to sea-level rise and storm surges. These same strategies, if well designed and well sited, have the potential to protect human communities from these threats as well. Conversely, addressing these threats to humans by building sea walls will not offer the co-benefit to nonhuman species and systems. As a second example of a co-benefit, riparian restoration has the potential to reduce stream temperatures through shading and may also increase water quality and water storage for human use.

To develop strategies that maximally benefit both nonhuman and human systems and communities, it will be necessary to develop approaches for evaluating and comparing co-benefits. As of yet, little work has been done in this area, in part because it involves measuring and weighing disparate outcomes and values and because it involves collaboration and coordination across diverse disciplines. Nonetheless, such comparative metrics and analyses will be quite useful for developing strategies and prioritizing among them.

Conclusions

Addressing climate-change impacts on terrestrial species will require at least a basic understanding of how climate change will affect species. Much is already known about climate effects on phenologies, distributions, populations, interspecific interactions, and diseases and pathogens. Although there are

significant gaps in the knowledge of these effects, detailed studies of potential climate impacts on specific species are not likely to provide managers and policy makers with the most critical information for developing adaptation strategies for terrestrial species. On the contrary, research focused on developing actionable adaptation strategies from the many general concepts and basic principles that have been proposed for addressing climate change has the potential to inform the management of a wide range of species and systems. For example, research focused on approaches to adaptive management, refining triage systems, connecting landscapes to facilitate range shifts, and measuring and valuing the co-benefits of adaptation strategies for human and nature systems will be critical components of a research agenda for addressing climate impacts on terrestrial species and systems (Table 1).

Glossary

Climatic models Mathematical descriptions of the flows of energy, momentum, and materials around the atmosphere and oceans, typically run on large computers to stimulate the Earth's climate naturally and when disturbed by greenhouse gases or other so-called forcings or disturbances.

Global-change disturbances Alterations or disturbances to the natural conditions of the global atmosphere (e.g., greenhouse gases produced by human activities) or to enough regions (e.g., large-scale deforestation or the widespread introduction of exotic, invasive species in many places throughout the world) to have global impacts.

Global warming The additional heating of the Earth's climate from the incremental injection of greenhouse gases to the atmosphere from human activities such as deforestation or fossil fuel consumption.

Greenhouse gases Gases in the atmosphere, which selectively let more of the solar energy into and out of the atmosphere than they permit the transmission of long-wave infrared radiation. They contribute to the greenhouse effect, which traps radiant energy in the lower atmosphere and makes the Earth warmer.

Synergisms Interactions among many factors, which collectively may have a much larger or smaller effect than the sum of the effects of each factor acting independently.

"Climate Change and Ecology, Synergism of" is adapted from Schneider and Root (1998).

Synergisms of Climate Change and Ecology

The Earth's climate is vastly different now from what it was 100 million years ago (Mya) when dinosaurs roamed the planet and tropical plants thrived closer to the poles. It is different from what it was 20,000 years ago when ice sheets covered much of the Northern Hemisphere. Although the Earth's climate will surely continue to change, climatic changes in the distant past were driven by natural causes, such as variations in the Earth's orbit or the carbon dioxide (CO₂) content of the atmosphere. Today and in the future, climatic changes have had and will quite likely continue to have another source as well – human activities. Humans cannot directly rival the power of natural forces driving the climate, for example, the immense energy input to the Earth from the sun that powers the climate. We can, however, indirectly alter the natural flows of energy enough to create significant climatic changes. The best-known way people inadvertently modify climate is by enhancing the natural capacity of the atmosphere to trap radiant heat near the Earth's surface – the so-called greenhouse effect. This natural phenomenon allows solar energy to reach the Earth's surface and warm the climate. Gases such as water vapor and CO₂ trap a large fraction of long-wavelength radiant energy called terrestrial infrared radiation near the Earth's surface. This causes the natural greenhouse effect to be responsible for approximately 33 °C (60 °F) of surface warming. Thus, seemingly small human-induced changes to the natural greenhouse effect are typically projected

to result in a global warming of 1.1–6.4 °C or higher by 2100 (IPCC, 2007a). It is highly likely that this could result in ecologically significant changes, which is why climatic considerations are fundamental in the discussion of the status and trends of ecological conditions.

We are already feeling the climatic effects of us having polluted the atmosphere with gases such as CO₂ (IPCC, 2007a). Many activities associated with human economic development have changed the physical and chemical environment in ways that modify natural resources. As these changes, such as burning fossil fuels that release CO₂ or using land for agriculture or urbanization that causes deforestation, have become large enough, significant global (worldwide) changes have occurred and are expected to continue. Such modifications can disturb the natural flows of energy in Earth's systems and thus can force significant climatic changes. These disturbances are also known as global-change forcings. Quantitative evaluations of the potential effect of human activities in creating global change are needed. Such evaluations are also central to potential policy responses to mitigate global changes (Schneider, 1997; IPCC, 2001c, 2007c).

Synergisms

One of the most potentially serious global-change problems is the synergistic or combined effects of habitat fragmentation and climate change. People fragment natural habitats for farmland, settlements, mines, roads, and other developmental activities. As climate changes, individual species of plants and animals are forced to adjust if they can, as they have in the past by tracking their preferred temperatures by moving into historically cooler locations. It seems unlikely that all of the species that moved into historically warmer locations to survive the Ice Age will be able to safely reach refuges due to the

[†]Deceased.

necessity of migrating across freeways, agricultural zones, industrial parks, military bases, and cities of the twenty-first century. An additional complication arises with the imposition of the direct effects of changes in CO₂, which can change terrestrial and marine primary productivity as well as alter the competitive relations among photosynthesizing organisms.

One representative instance of synergism is that of the Kirtland's warbler in northern Michigan; this species is restricted to a narrow area of jack pines that grow in sandy soil (Botkin *et al.*, 1991). Forest gap models of growth and decline of jack pines indicate that this tree will move north with warming, but the Kirtland's warbler will not likely survive the transition. This bird nests on the ground under relatively young pines, and the soil to the north is not generally sandy enough to allow sufficient drainage for successful fledging of young (Anich *et al.*, 2011). Consequently, global warming could well doom the warbler to extinction in 30–60 years. This potential for extinction indicates how the already high rate of extinctions throughout the world could be exacerbated by climatic changes occurring more rapidly than species can adapt (Pimm *et al.*, 2006; Pereira *et al.*, 2010; Barnosky *et al.*, 2011).

The synergism question raises a controversial management problem of anticipating global-change risk and responding by setting up interconnected nature reserves to ensure against some species becoming extinct as the climate changes. Alternatively, we could simply let the remnants of relatively immobile wildlife and natural plant communities remain in isolated reserves and parks as now exist, which could doom them to extinction in the isolated areas. If we do opt for more environmental safeguards by interconnecting our parks, the question then becomes how do we interconnect the nature reserves? Priorities must be set and money made available for constructing natural corridors through which species can travel. For example, elevated sections of highways may be needed to allow for migration routes, similar to what was done for the caribou in the Arctic when the Alaskan pipeline was built. To examine such questions as these in scientific detail, it is first necessary to make a multidisciplinary examination of the subcomponents of the various aspects of climatology and ecology. We begin with a background discussion of climatic history, processes, modeling, and validation, as a prelude to focus on ecological processes, that need to be examined in order to project possible synergisms between ecology and climate change.

Climate History: What Has Happened?

Scientists can reconstruct the cyclical expansion and contraction of polar caps and other ice masses using ice core samples taken from Greenland and Antarctica. When snow falls on high, cold glaciers the air trapped between snow grains is eventually transformed into air bubbles as the snow is compressed into ice from the weight of subsequent accumulations. The ratio of two oxygen molecules with different molecular weights (O¹⁶ and O¹⁸ isotopes) is a proxy record for the temperature conditions that existed when the snow was deposited. From this, scientists have been able to determine that the ice buildup from 90,000 to 20,000 years ago was quite variable and was followed by a (geologically speaking) fairly

rapid 500- to 10,000-year transition to the (current) climatically very stable Holocene Period. The Holocene is the 10,000-year interglacial period in which human civilization developed and modern plant and animal distributions evolved to their current states. These ice cores also provide information on the presence of CO₂, an important greenhouse effect gas. Carbon dioxide was in much lower concentrations during cold periods than in interglacials (which is also similar for the greenhouse gas methane, CH₄). This implies an amplifying effect, or a positive feedback, because lower amounts of these gases during cold glacial periods means less trapped infrared radiative heat, thereby amplifying the cooling, and vice versa, during warm interglacial periods. The ice cores also show that concentrations of CO₂ and CH₄ and temperature were remarkably constant for about the past 10,000 years (but before AD 1700), particularly when compared with the longer record. That relative constancy in chemical composition of the greenhouse gases held until the industrial age during the past two centuries.

The transition from Ice Age to the Holocene took 5000–10,000 years, during which time the average global temperature increased 5–7 °C and the sea-level rose 100 m. Thus, we estimate that natural rates of warming on a sustained global basis are about 0.5–1 °C per thousand years. Such changes were large enough to have radically influenced where species lived (Graham, 1992) and to have potentially contributed to the well-known extinctions of woolly mammoths, sabertooth cats, and enormous salamanders.

A large interdisciplinary team of scientists, including ecologists, palynologists (scientists who study pollen), paleontologists (scientists who study prehistoric life, especially fossils), climatologists, and geologists, formed a research consortium (Cooperative Holocene Mapping Project, 1988; Wright *et al.*, 1993) to study the dramatic ecological changes accompanying the transition from Ice Age to the recent interglacial period. One group of these researchers used a variety of proxy indicators to reconstruct vegetation patterns over the past 18,000 years for a significant fraction of the Earth's land areas. In particular, cores of fossil pollen from dozens of sites throughout North America clearly showed how boreal tree pollen, now the dominant pollen type in the boreal zone in central Canada, was a prime pollen type during the last Ice Age (15,000–20,000 years ago) in what are now the mixed hardwood and Corn Belt regions of the US. During the last Ice Age, most of Canada was under ice; pollen cores indicate that as the ice receded, boreal trees moved northward chasing the ice cap. One interpretation of this information was that biological communities moved intact with a changing climate. In fact, Darwin (1859) asserted as much:

As the arctic forms moved first southward and afterward backward to the north, in unison with the changing climate, they will not have been exposed during their long migrations to any great diversity of temperature; and as they all migrated in a body together, their mutual relations will not have been much disturbed. Hence, in accordance with the principles inculcated in this volume, these forms will not have been liable to much modification.

If this were true, the principal ecological concern over the prospect of future climate change would be that human land-use patterns might block what had previously been the

free-ranging movement of natural communities in response to climate change. The Cooperative Holocene Mapping Project, however, incorporated multiple pollen types into its analyses, including not only boreal species but also herbs and more arid (xeric) species as well as oaks and other mesic species. They discovered that during the transition from the last Ice Age to the present interglacial, nearly all species moved north, as expected. During a significant portion of the transition period, however, the distribution of pollen types provided no analog associations to today's vegetation communities (Overpeck *et al.*, 1992), that is, whereas all species moved, they did so individual by individual, not as community groups. Consequently, the groupings of species during the transition period were often dissimilar to those present today (Figure 1). The relevance of this conclusion is that in the future ecotypes will not necessarily move as a unit as climate changes (assuming there is enough time and space for such a migration). Past vegetation response to climatic change at an average rate of 1 °C per millennium indicates that credible predictions of vegetation changes from comparable or even more rapid climatic changes projected from human activities cannot neglect transient (i.e., time-evolving) dynamics of the ecological system. Furthermore, caution should be exercised against relying too much on past conditions in forecasting future patterns resulting from global-change forcings because the forecasted global average rate of temperature increase far exceeds those rates typical of the past 120,000 years.

Future climates may not only be quite different from more recent previous climates but may also be different from those inferred from paleoclimatic data and from those to which some existing species are evolutionarily adapted. Therefore, possible future changes inferred from past changes can be taken only as a guide or a means to verify aspects of the forecasts of models of climate or ecosystem dynamics (Crowley, 1993; Schneider, 1993a). Such verification exercises may provide more credible forecasts of the effects of climatic change on animals.

Forces of Climate Change

The two basic categories of causes of climatic change are external and internal. However, these terms are defined relative to the focus of study; stating which components are external or internal to the climatic system depends on the time period and spatial scale being examined, as well as the phenomena being considered. External causes of climate change do not have to be physically external to the Earth (such as the Sun) but do occur outside of the climate system. If our focus is on atmospheric change on a 1-week time scale (i.e., the weather), the oceans, land surfaces, biota, and human activities that produce CO₂ are all external (i.e., they are not influenced much by the atmosphere in such a short time). If our focus is on 100,000-year Ice Age interglacial cycles, however, the oceans, ice sheets, and biota are all part of the internal climatic system and vary as an integral part of the Earth's environmental systems. On this longer scale we must also include as part of our internal system the solid earth, which really is not solid but viscous and elastic.

Fluctuations in heat radiated by the Sun – perhaps related to varying sunspots – are external to the climate system. Influences of the gravitational tugs of other planets on the Earth's orbit are also external. Human-caused changes in the Earth's climate could not perceptibly alter either one of these cycles.

Carbon dioxide and methane levels rise and fall with Ice Age cycles, which are clearly internal on a 10,000-year time scale. However, on a 20-year scale these greenhouse gases become largely an external cause of climatic change, because small changes in climate have little feedback effect on, for example, humans burning fossil fuel.

Changes in the character of the land surface, such as those caused by human activities, are largely external. If vegetation cover changes because of climatic change, however, land surface change then becomes internal because changes in plant cover can influence the climate by changing albedo (reflectivity to sunlight), evapotranspiration, surface roughness, and relative humidity (Henderson-Sellers *et al.*, 1993).

Snow and ice are important factors in climatic change because they have higher albedo (reflectivity) than warmer surfaces and, in the instance of sea ice, can inhibit transfer of heat and moisture between air and wet surfaces. Salinity, which affects changes in sea ice and in the density of seawater, which helps control where ocean waters sink, may also be an internal cause of climatic variation. The sinking and upwelling of ocean waters are biologically significant because the upwelling waters are often nutrient-rich.

Unusual patterns of ocean surface temperature, such as the El Niño, demonstrate the importance of internally caused climatic fluctuations because the atmospheric circulation can change simultaneously with ocean surface temperatures. When the atmosphere rubs on the ocean, the ocean responds by modifying its motions and temperature pattern, which forces the atmosphere to adjust, which changes the winds, which changes the way the atmosphere rubs on the ocean, and so forth (Trenberth, 1992). As a result, air and water interact internally in this coupled system like blobs of gelatin of different size and stiffness connected by elastic bands or springs, all interacting with one another while also being pushed from the outside (by solar, volcanic, or human-caused change).

Climate Change Projections: What Will Happen?

To predict the ecologically significant ways the climate might change, one must specify what people do that modifies how energy is exchanged among the atmosphere, land surface, and space because such energy flows are the driving forces behind climate. Air pollution is an example of such a so-called societal forcing of the climate system. Estimating societal forcing involves forecasting a plausible set of human (or societal) activities affecting pollution from now until 2100. The next step is to estimate the response of the various components of the earth system to such societal forcings. The earth system consists of the following interacting subcomponents: atmosphere, oceans, cryosphere (snow, seasonal ice, and glaciers), and land-surface (biota and soils) systems.

Research in the field and in laboratories provides an understanding about various processes affecting the subcomponents

Ice
 Tundra
 Forest tundra
 Boreal forest
 Mixed forest
 Deciduous forest
 Aspen parkland
 Prairie
 Southeast forest
 No analog
 No data

Figure 1 Selected paleovegetation maps reconstructed using the method of modern analogs and more than 13,000 samples of fossils and modern pollen: (a) 18,000 BP, (b) 12,000 BP, (c) 6000 BP, and (d) modern. No vegetation is mapped in areas without fossil pollen data, and no analog refers to vegetation without any modern analog. Reproduced from Overpeck JT, Webb RS, and Webb III T (1992) Mapping eastern North American vegetation change over the past 18,000 years: No analogs and the future. *Geology* 20: 1071–1074, with permission from Geological Society of America Bulletin.

of the earth system. This understanding can be put into mathematical expressions that, when combined, form a model of the behavior of particular components of the earth system. In practice, models of the atmosphere are connected to models of the oceans, ice, biota, and land surfaces to simulate the consequences of a scenario of societal forcing on climate and ecosystems. Controversy arises because both the societal forcing that will actually occur and the scientific knowledge of each subsystem are incomplete. Because models cannot be perfect replicas of the actual natural system, scientists must expend considerable efforts to test their models against the expanding base of field and laboratory data. This not only allows them to assess the robustness of current simulations but it also reveals improvements for the next generation of models.

Elements of Global Warming Forecasts

The societal driving forces behind global-warming scenarios are projections of population, consumption, land use, and technology. Typical twenty-first-century projections for human population size and affluence for less highly developed countries and more highly developed countries show drastic increases in population and wealth. When these factors are multiplied by the amount of energy used to produce a unit of economic product (the so-called energy intensity) and the amount of CO₂ emitted per unit of energy (the technology factor called carbon intensity), carbon emissions are predicted to increase several fold throughout the twenty-first century. It is very difficult to make such projections credibly; therefore, analysts disagree by as much as a factor of 10 about how much CO₂ will be emitted by 2100 (IPCC, 2007a). Specific scenarios are debatable because the amount of carbon emitted through human activities will significantly depend on what kinds of energy systems will be developed and deployed globally and on what the standards of living will be during the next several decades, not to mention population growth.

To turn estimates of CO₂ emissions into estimates of CO₂ concentrations in the atmosphere – the variable needed to calculate potential climate changes – one must estimate what fraction of CO₂ emitted will remain in the atmosphere. This airborne fraction is most simply estimated at 45% because the amount of CO₂ buildup in the atmosphere each year is about half the fossil fuel-injected CO₂ with the other part being absorbed by ocean and biosphere. The atmospheric concentration of CO₂, however, should be computed using carbon-cycles models, which account for the time-evolving amounts of carbon in vegetation, soils, and oceanic and atmospheric subcomponents (IPCC, 2007a). The estimated CO₂ concentration can then be fed into computerized climatic models to estimate its effects on climate.

Climate prediction, like most other forecasts involving complex systems, generally involves educated guesses. Those attempting to determine the future behavior of the climate system from knowledge of its past behavior and present state basically can take two approaches. One approach, the empirical–statistical, uses statistical methods such as regression equations that connect past and present observations statistically to obtain the most probable extrapolation. The

second approach, usually called climate modeling, focuses on first principles, which are equations representing laws believed to describe the physical, chemical, and biological processes governing climate. Because the statistical approach depends on historical data, it is obviously limited to predicting climates that have been observed or are caused by processes appropriately represented in the past conditions. The statistical method cannot reliably answer questions such as what would happen if atmospheric CO₂ increased at rates much faster than in the known past. Thus, the more promising approach to climate prediction for conditions or forcings different from the historic or ancient past is climate modeling. A significant component of empirical–statistical information, though, is often embedded into these models (Root and Schneider, 1995). This often makes modelers uncomfortable about the validity of predictions of such models on unusual or unprecedented situations unless a great deal of effort is expended to test the models against current and paleoclimatic baseline data.

Climate models vary in their spatial resolution – that is, the number of dimensions they simulate and the spatial detail they include. The simplest model calculates only the average temperature of the Earth, independent of the average greenhouse properties of the atmosphere. Such a model is zero-dimensional: It reduces the real temperature distribution on the Earth to a single point, a global average. In contrast, three-dimensional climate models produce the variation of temperature with latitude, longitude, and altitude. The most complex atmospheric models, the general circulation models (GCMs), predict the time evolution of temperature plus humidity, wind, soil moisture, sea ice, and other variables through three dimensions in space.

Verifying Climate Forecasts

The most perplexing question about climate models is whether they can be trusted as a reliable basis for altering social policies, such as those governing CO₂ emissions or the shape and location of wildlife reserves. Even though these models are fraught with uncertainties, several methods are available for verification tests. Although no method is sufficient by itself, several methods together can provide significant, albeit circumstantial, evidence of a forecast's credibility.

The first validation testing method involves checking the model's ability to simulate the current climate. The seasonal cycle is a good test because temperature changes in a seasonal cycle are larger on a hemispheric average than the change from an Ice Age to an interglacial period (i.e., 15 °C seasonal range in the Northern Hemisphere versus 5–7 °C glacial–interglacial cycle). GCMs map the seasonal cycle well. This supports the scientific consensus about the plausibility of global warming of several degrees in the twenty-first century. The seasonal test, however, does not indicate how well a model simulates slow processes such as changes in deep-ocean circulation, ice cover, forests, or soil carbon storage, which may have important effects on the decade- to century-long timescales over which atmospheric CO₂ is expected to double.

A second verification technique involves isolating individual physical components of the model and testing them

against actual data. A reasonable model should reproduce the flow of thermal energy among the atmosphere, the surface, and space with no more than about a 10% error. Together, these energy flows make up the well-established natural greenhouse effect on Earth and constitute a formidable and necessary test for all models. A model's performance in simulating these energy flows is an example of physical validation of model components.

A third validation method involves the model's ability to reproduce the diverse climates of the past. This method is aided by recorded instrumental observations made during the past few centuries and paleo-records that serve as a proxy for climatic conditions of the ancient earth, or even include testing the models' ability to simulate climates of other planets (Kasting *et al.*, 1988). Paleoclimatic simulations of the Mesozoic (Age of the Dinosaurs), glacial-interglacial cycles, or other extreme past climates help scientists understand the coevolution of the Earth's climate and living things (Schneider and Londer, 1984). As verification tests of climate models, they are also crucial in predicting future climates and changes in biological systems.

Using these techniques, much has been learned from examining the global climatic trends of the past century. Northern Hemisphere surface temperature increased more during the twentieth century than during any other century in the past 1000 years. The 1990s was the warmest decade of the millennium, and the first decade of the twenty-first century has been even warmer, with nine of the 10 warmest years on record occurring in the twenty-first century. These data are consistent with an enhanced greenhouse effect signal that might be anticipated from the greenhouse gas injections during the past 250 years, which saw a 36% increase in CO₂, a ~160% increase in CH₄, and the introduction of human-generated heat-trapping chemicals such as chlorofluorocarbons and halons. Industrial activities since the 1950s have contributed to the increase of sulfur dioxide and other aerosol particles into the atmosphere, which reduce surface temperature by reflecting sunlight back to space. Although such cooling effects may have counteracted global warming by only several tenths of a degree, the hazes occur regionally and could be producing ecologically significant, unexpected regional changes in climate patterns (Schneider, 1994).

Although the 0.7 ± 0.2 °C surface warming in the twentieth century is consistent with the human-induced greenhouse gas buildup, it is possible that the 0.7 °C warming trend was wholly natural and that there was little or no contribution from the buildup of greenhouse gases (for estimates of the probability of human-induced global warming amounts, see Morgan and Keith (1995)). However, it is also not possible to rule out the counterfactual that, independent of the enhanced greenhouse effect due to human activity, there was a natural cooling fluctuation taking place during the twentieth century. If so, the world would then have warmed up much more than observed had we not had a fortuitous natural cooling trend. One could even speculate that the dramatic temperatures since the 1970s with global high temperature records reflect the termination of a natural cooling trend combined with the rapid establishment of the expected enhanced greenhouse effect.

Studies (Santer *et al.*, 1996) suggest that when aerosols and greenhouse gas forcings are combined, climate models more

closely match 30 years of observations. Nevertheless, there is wide variability in predictions for a doubling of CO₂: Temperature changes as low as a 0.5 °C warming to as high as a 5.0 °C warming (Wigley and Raper, 1991) are all consistent with current observations. Several reasons exist for such a wide range of uncertainty: difficulty in knowing how to model delays in global warming because of the large heat capacity of the oceans; not knowing what other global-change forcings may have opposed warming, for example, sulfate aerosols from burning high-sulfur coal and oil or undetectable changes in the Sun's light output before 1980; and large, unknown, internal natural climatic fluctuations. As mentioned previously, though, the ecologically important forecasts of time-evolving regional climatic changes are much less credible and require that ecologists use many alternative scenarios of possible climatic changes.

In summary, the warming of the globe is unequivocal and this is very likely due to human activities as its primary driver (IPCC, 2007a). This conclusion has emerged clearly from studies done since 1995 when the Intergovernmental Panel on Climate Change (1996a) carefully weighed the uncertainties and concluded that "the balance of evidence suggests that there is a discernible human influence on global climate."

Relevance of Climate Modeling to Regional Climate Change and Ecosystem Studies

Scientists who estimate the future climatic changes that are relevant to ecosystems have focused on the GCMs that attempt to represent mathematically the complex physical and chemical interactions among the atmosphere, oceans, ice, biota, and land. As these models have evolved, increasingly more information has become available, and more comprehensive simulations have been performed. Nevertheless, the complexities of the real climate system still vastly exceed the GCMs and the capabilities of even the most advanced computers (Intergovernmental Panel on Climate Change, 1996a, 2007a). Simulating a 50-year projection of climate with a grid size of 100 km on a side and 20 vertical layers – about 2,500,000 grid points – takes several months on a supercomputer. This level of resolution, however, cannot resolve the Sierra Nevada of California and the Rocky Mountains as separate mountain chains. Refining the resolution to 50-km grid squares would so dramatically increase the number of computations that it would take many more months of computer time to simulate weather statistics for 1 year.

Even the highest-resolution, three-dimensional general circulation model will not have a grid with nodes much less than 100-km apart within the foreseeable future; individual clouds and most ecological research (to say nothing of cloud droplets) occur on scales far smaller. Therefore, GCMs will not be able to resolve the local or regional details of weather affecting most local biological communities or the importance of regional effects of hills, coastlines, lakes, vegetation boundaries, and heterogeneous soil (Root and Schneider, 1993). Nonetheless, it is important to have climatic forecasts and ecological-response analyses on the same physical scales.

What is most needed to evaluate potential biological effects of temperature change is a regional projection of climatic

changes that can be applied to ecosystems at a regional or local scale. Analyses of large, prehistoric climatic changes (Schneider, 1987; Cooperative Holocene Mapping Project, 1988) and historical weather analogs (Shabalova and Konnen, 1995) provide some insights into such changes. Historical weather analogs, however, since they are empirically and statistically based, rely on climatic cause-and-effect processes that probably differ from those that will be driven by future greenhouse gas radiative effects (Schneider, 1984; Crowley, 1993). Consequently, ecologists turn to climatic models to produce forecasts of regional climatic changes for the decades ahead. How credible are such forecasts?

Regional Changes

Although the consensus among researchers about the plausibility of significant human-induced global climatic change is growing, no assessment (Intergovernmental Panel on Climate Change, 1996a) has suggested the existence of a strong consensus about how that global climatic change might be distributed regionally. The world is undergoing a steady increase in greenhouse gas forcing. Because that increase is heating the Earth in a reasonably uniform way, one might expect a uniform global response, although this is far from likely. For example, the centers of continents have relatively low heat-retaining capacity, and the temperatures there would move relatively rapidly toward whatever their new equilibrium climate would be compared with the centers of oceans, which have high heat-retaining capacity. Tropical oceans, though, have a thin (about 50 m) mixed layer that interacts primarily with the atmosphere. It takes about 10 years for that mixed layer to substantially change its temperature, which is still much slower than the response time of the middle of the continents but is much faster than that of the oceans closer to the poles. At high latitudes, in places such as the Weddell or Norwegian seas, waters can mix down to the bottom of the ocean, thereby continuously bringing up cold water and creating a deep-water column for which a century or more is required to substantially change its temperature.

During the transient phase of climate change over this century, therefore, one would expect the middle of continents, the middle of oceans, and the polar and subpolar oceans all to change toward their new equilibrium temperatures at different rates. Thus, the temperature differences from land to sea and equator to pole will evolve over time, which in turn implies that the transient character of regional climatic changes could be very different from the expected long-term equilibrium (Schneider and Thompson, 1981; Washington and Meehl, 1986). This does not imply that transient regional changes are inherently unpredictable, only that currently they are very difficult to predict credibly.

Even more uncertain than regional averages, but perhaps more important to long-term ecosystem responses, are estimates of climatic variability during the transition to a new equilibrium, particularly at the regional scale. These include estimates of events such as the frequency and magnitude of severe storms, enhanced heat waves, temperature extremes, sea-level rises (Titus and Narayanan, 1996), and reduced frost probabilities (Rind *et al.*, 1989). For example, there is a

physical principle that evaporation increases dramatically as surface-water temperature increases. Because hurricanes are powered by evaporation and condensation of water, if all other factors are unchanged, the intensity of hurricanes and the length of the hurricane season could increase with warming of the oceans (Emanuel, 2003, 2006; Trenberth, 2005). Such changes would significantly affect susceptible terrestrial and marine ecosystems.

Downscaling Climate Predictions to Regional Effects

Empirical Mapping Techniques

Techniques exist that can translate the output of climate models so that it is closer to that of most ecological scales. One method that uses actual climatic data at both large and small scales can help provide maps that may allow small-scale analysis of large-scale climate change scenarios. For example, the Sierra Nevada of California or the Cascades in the northwestern US are north-south mountain chains whose east-west dimensions are smaller than the grid size of a typical general circulation model. In the actual climate system, onshore winds on the Pacific coast would produce cool upslope and rainy conditions on the western slope and a high probability of warmer and drier conditions associated with that flow pattern on the downslope or eastern slope.

Regional maps have been generated for Oregon (Gates, 1985) in which a high-resolution network of meteorological stations was used to plot temperature and precipitation isopleths based on observed climatic fluctuations at large (e.g., state-sized) scales. These maps show that the dominant mode of variation for this area is warm and dry on one side of the mountains and cold and wet on the other side. Although this empirical mapping technique seems appropriate for translating low-resolution, grid-scale climate-model forecasts to local applications, a strong caveat must be offered, that is, the processes in the climate system that give rise to internal variability or natural fluctuations are not necessarily the same processes that would give rise to local deviations from large-scale patterns if the climate change were driven by external forces rather than an internal variation of the system. For example, the Oregon maps would indicate that if the grid box average temperature were warmer on the eastern slope, then it should be cooler and wetter on the western slope. This condition is the most probable regional situation for today's naturally fluctuating climate. However, if 50 years from now the warming on the eastern slope were, for example, a result of doubled atmosphere CO₂ causing an enhanced downward infrared radiative heating, then both eastern and western slopes would probably experience warming. Although the degree of warming and associated precipitation changes would not necessarily be uniform, an entirely different climatic change pattern would probably occur as opposed to that obtained from the empirical mapping technique if one used the naturally varying weather conditions existing today rather than the anthropogenically forced conditions of the twenty-first century (Schneider, 1993b).

Therefore, techniques to downscale climate forecasts that use current distributions of environmental variables at local scales and correlate them with current large-scale regional

patterns may not necessarily provide a good guideline about how large-scale patterns would be distributed regionally. This is especially true if there are changes in prevailing winds, seasonality, or cloud cover. The reason is that the causes of the future change may be physically or biologically different from the causes of the historical fluctuations that led to the empirical maps in the first place. This caveat warns scientists to use caution before adopting such empirical techniques for global-change applications.

There are practical limits to downscaling, especially using global techniques. Downscaling to a weather station, assuming that the weather-station data are accurate (a dubious assumption in many parts of the world and the above caveats are heeded), provides useful information at the level of the point. Gridded weather data are often used when weather-station data are not available. These grids are typically $0.5^\circ \times 0.5^\circ$ of latitude and longitude in size, but the uncertainties in gridding areas with sparse data and with large elevational changes must be recognized. The standard gridded data set used in many studies is the CRU TS data (University of East Anglia Climate Research Unit). In some areas with large numbers of weather stations (e.g., US, Europe, and Australia) smaller grids (approximately 10 km^2) have been developed (e.g., VEMAP, OzClim). Although it is theoretically possible to downscale to such small scales and even smaller ones (1 km^2 based on digital elevation model data), caution must be taken when using any of these gridded data. At a large scale (50 km^2) the differences in slopes of mountains are rarely picked up. At 1 km^2 , elevation is important, but slopes, aspect and, especially wind direction and water transport, are essential when calculating lapse rate to estimate temperature and vital for precipitation estimates.

Regional-Scale Models with GCM Inputs

Other techniques can still translate large-scale patterns to smaller scales, but these techniques are based on known processes rather than empirical maps for today's conditions. One such technique is to drive a high-resolution, process-based model for a limited region with the large-scale patterns produced by a GCM. In essence, this approach uses a mesoscale model (i.e., 10- to 50-km^2 grid cells) based on physical laws to solve the problem of translating GCM grid-scale averages into a finer scale mesh much closer to the dimensions of most ecological applications. Of course, even this mesoscale grid will still be too coarse to assess many impacts, necessitating further downscaling techniques. Neither are the problems of GCMs entirely eliminated by mesoscale grids because they are still bigger than individual clouds or trees. However, such methods do bring climate-model scales and ecological-response scales much closer.

Examples of Ecological Responses to Climate Changes

Bringing climatic forecasts to ecological applications at local and regional scales is one way to bridge the scale gap across ecological and climatological studies (IPCC, 2001b, 2007b). Ecologists, however, have also analyzed data and constructed models that apply over large scales, including the size of

climatic model grids. A long tradition in ecology has associated the occurrence of vegetation types or the range limits of different species with physical factors such as temperature, soil moisture, land-sea boundaries, or elevation. Biogeography is the field that deals with such associations, and its results have been applied to estimate the large-scale ecological response to climate change.

Predicting Vegetation Responses to Climate Change

The Holdridge (1967) life zone classification assigns biomes (e.g., tundra, grassland, desert, or tropical moist forest) according to two measurable variables – temperature and precipitation. Other more complicated large-scale formulas have been developed to predict vegetation patterns from a combination of large-scale predictors (e.g., temperature, soil moisture, or solar radiation); vegetation modeled includes individual species (Davis and Zabinski, 1992), limited groups of vegetation types (Schimel *et al.*, 2001), or biomes (Steffen *et al.*, 1996). These kinds of models predict vegetation patterns that represent the gross features of actual vegetation patterns, which are an incentive to use them to predict vegetation change with changing climate, but they have some serious drawbacks as well, that is, they are typically static, not time-evolving dynamic simulations, and thus cannot capture the transient sequence of changes that would take place in reality. In addition, such static biome models occasionally make “commission errors;” that is, they typically predict vegetation types to occur in certain zones where climate would indeed permit such vegetation, but other factors such as soils, topography, or disturbances such as fire or land-use change actually preclude it. However, newer dynamic general vegetation models (DGVMs) have started to include disturbance regimes. These DGVMs, which work at the level of the plant functional type (PFT, similar to biomes), have been used to look at potential changes in net primary productivity as well as changes in plant groups over time. One of the problems with using DGVMs in a predictive sense is that they are typically on or off – that is, they show what the current PFT might be and what the future PFT might be but they lack a transition state. This can be misleading for policymakers as it misses the critical information both as to the longevity of some of these PFTs in the absence of disturbance (i.e., reproduction stops but individuals persist for the lifetime of the organisms, potentially several hundred years) as well as the slow rate of dispersal for many plant species. Thus a transition state, matching neither the current nor future PFT is likely. This can be overcome, to some extent by looking at individual species but the large number of species involved, until recently, has made it difficult to look at changes at this scale. The access of large clusters of computers and global data sets, however, has meant that large-number-of-species models can now be run. For example, one particular effort called the Wallace Initiative has modeled almost 50,000 terrestrial plant and animal species. Furthermore, local patterns may influence vegetation dynamics at scales not captured in some simulations, and seed germination and dispersal mechanisms are also either not explicitly simulated or simulated only crudely with such models. It is remarkable that they are still able to produce

generalized maps of vegetation types that do indeed resemble current or even paleoclimatic patterns in a broad sense, but their details do not provide confident projections for future vegetation states. Fortunately, progress is being made to include some of the deficiencies mentioned previously, and the so-called dynamical global vegetation models are being developed to treat the transient nature of vegetation change that would likely accompany climatic change.

Predicting Animal Responses to Climate Change

Scientists of the US Geological Survey, in cooperation with Canadian scientists, conduct the annual North American Breeding Bird Survey, which provides distribution and abundance information for birds throughout the US and Canada. From these data, collected by volunteers under strict guidance from the US Geological Survey, shifts in bird ranges and abundances can be examined. Because these censuses were begun in the 1960s, these data can provide a wealth of baseline information. Price (1995) used these data to examine the birds that breed in the Great Plains. Using the present-day ranges and abundances for each of the species (Figure 2(a)), Price derived large-scale, empirical–statistical models based on various climate variables (e.g., maximum temperature in the hottest month and total precipitation in the wettest month) that provided estimates of the current bird ranges and abundances (Figure 2(b)). Then, using a general circulation model to forecast how doubling of CO₂ would affect the climate variables in the models, Price applied the statistical models to predict the possible shape and location of the birds' ranges and abundances (Figure 2(c)).

Significant changes were found for nearly all birds examined. The ranges of most species moved north, up mountain slopes, or both. The empirical models assume that these species are capable of moving into these more northerly areas, provided habitat is available and no major barriers exist. Such shifting of ranges and abundances could cause local extinctions in the more southern portions of the birds' ranges, and, if movement to the north is impossible, extinctions of entire species could occur. We must bear in mind, however, that this empirical–statistical technique, which associates large-scale patterns of bird ranges with large-scale patterns of climate, does not explicitly represent the physical and biological mechanisms that could lead to changes in birds' ranges. Therefore, the detailed maps should be viewed only as illustrative of the potential for very significant shifts with different possible doubled CO₂ climate change scenarios. More refined techniques that also attempt to include actual mechanisms for ecological changes are discussed later. Many think that birds may be able to keep up with rate of climate change because they can fly. However, rates of natal dispersal should not be confused with the expansion capability of populations. A review of the literature on dispersal rates (both historical and current) suggests that the range dispersal rate of birds and mammals is about the same – approximately 1–4 km per year.

Reptiles and amphibians are different from birds in many ways that are important to our discussion. First, because amphibians and reptiles are ectotherms – meaning that their body temperatures adjust to the ambient temperature and

radiation of the environment – they must avoid environments in which temperatures are too cold or too hot. Second, amphibians must live near water not only because the reproductive part of their life cycle is dependent on water but also because they must keep their skin moist because they “breathe” through their skin as well as their lungs. Third, neither reptiles nor amphibians are able to disperse as easily as birds because they must crawl rather than fly, and the habitat through which they crawl must not be too dry or otherwise impassable (e.g., high mountains or superhighways).

As the climate changes, the character of extreme weather events, such as cold snaps and droughts, will also change (NOAA), necessitating relatively rapid habitat changes for most animals. The role of extreme events and climate variability is still not adequately taken into account in models of species ranges. Although the climate change extinction-rate estimates are often criticized, it needs to be borne in mind that these are based on MEAN climates. Even the variables taken as extreme are normally not true extremes, but are averages over more than a month. Mortality in species is often measured in x number of days exceeding a certain threshold (the same as for coral bleaching). Thus, because the return rates of these threshold events will increase as the climate warms, then extinctions, or at least local extirpations, may very well happen sooner than projected by changes in the mean.

In general, animals most likely to be affected earliest by climatic change are those for which populations are fairly small and limited to isolated habitat islands. As a result of human-generated landscape changes, many reptiles now fall into this category, as do many other animals. Indeed, temperature-dependent sex-determined species are especially likely to suffer from extreme sex ratio biases, and therefore their sensitivity to rapid climate change appears potentially more severe than that of most other animals.

There are estimates that many small mammals living near isolated mountaintops (which are essentially habitat islands) in the Great Basin would become extinct given typical global-change scenarios (Beever *et al.*, 2011). Recent studies of small mammals in Yellowstone National Park show that statistically significant changes in both abundances and physical sizes of some species occurred with historical climate variations (which were much smaller than most projected climate changes for the next century), but there appear to have been no simultaneous genetic changes (Hadly *et al.*, 2004). Therefore, it is likely that climate change in the twenty-first century could cause substantial alteration to biotic communities, even in protected habitats such as Yellowstone National Park.

Top-Down Approaches

The biogeographic approach previously summarized is an example of a top-down technique (e.g., Holdridge life zone classification), in which data on abundances or range limits of vegetation types or biomes are overlain on data of large-scale environmental factors such as temperature or precipitation. When associations among large-scale biological and climatic patterns are revealed, biogeographic rules expressing these correlations graphically or mathematically can be used to forecast changes in vegetation driven by given climate changes.

Figure 2 (a) Map of current range and abundance of the bobolink as determined from actual observations during the US Geological Survey Breeding Bird Survey and (b) map of current range and abundance of the bobolink as estimated from the empirical–statistical model. The high correspondence in patterns between the maps in (a) and (b) suggests that this model reliably captures many of the features of the actual observed range and abundance of this species as depicted in the map in (a). (c) Map of the forecasted range and abundance of the bobolink for climate change response of a model with doubled CO₂. This map illustrates the potential for very significant shifts that doubled CO₂ would cause.

Bottom-Up Approaches

Another traditional analysis and forecasting technique is often referred to as bottom-up. Small-scale ecological studies have been undertaken at the scale of a plant or even a single leaf (Idso *et al.*, 1993) to understand how, for example, increased atmospheric CO₂ concentrations might directly enhance photosynthesis, net primary production, or water-use efficiency. Most such studies indicate increases in all these factors – increases that some researchers have extrapolated to ecosystems (Ellsaesser, 1991).

However, at the scale of a forest, the relative humidity within the canopy, which significantly influences the evapotranspiration rate, is regulated by the forest. In other words, if an increase in water-use efficiency decreased the transpiration from each tree, the aggregate forest effect would be to lower relative humidity. This, in turn, would increase transpiration, thereby offsetting some of the direct CO₂/water-use efficiency improvements observed experimentally at the scale of a single leaf or plant. Regardless of the extent to which this forest-scale feedback effect will offset inferences made from bottom-up studies of isolated plants, the following general conclusion emerges: The bottom-up methods may be appropriate for some processes at some scales in environmental science, but they cannot be considered credible without some sort of validation testing at the scale of the system under study.

Combined Top-Down and Bottom-Up Approaches

To help resolve the deficiencies of the top-down biome forest models mentioned previously, more process-based, bottom-up approaches such as forest gap models have been developed (Ostle *et al.*, 2009). These models include individual species and can calculate vegetation dynamics driven by time-changing climatic change scenarios. However, the actual growth rate calculated in the model for each species has usually been determined by multiplying the ideal growth-rate curve by a series of growth-modifying functions that attempt to account for the limiting effects of nutrient availability, temperature stress, and so forth. These growth-modifying functions for temperature are usually determined empirically at a large scale by fitting an upside-down U-shaped curve, with maximum temperature midway between the average temperature of the species' northern range limit and the average temperature of its southern range limit. Growing degree-days (related to temperature but not temperature *per se*) are used in this scenario.

In essence, this technique combines large-scale, top-down empirical-pattern correlations into an otherwise mechanistic bottom-up modeling approach. Although this combined technique refines both approaches, it has been criticized because such large-scale, top-down inclusions are not based on the physiology of individual plant species and lead to confusion about the fundamental and realized niches (Pacala and Hurtt, 1993). (The fundamental niche is the ecological space in which a given species could theoretically survive – for example, if its competitors were absent – and the realized niche is where it actually exists.) The question is then, what limits the realized niche, particularly at the southern boundary? Furthermore, more refined models should include factors such

as seed dispersal so that plant recruitment is related to the preexisting population and is not simply the result of a random number generator in the computer code.

Studies of More Refined Approaches

As noted previously, problems with the singular use of either top-down or bottom-up methods have led to well-known criticisms. For bottom-up models, the primary problem is that some of the most conspicuous processes observable at the smaller scales may not be the dominant processes that generate large-scale patterns.

Top-down approaches suffer because of the possibility that the discovered associations at large scales are statistical artifacts that do not, even implicitly, reflect the causal mechanisms needed for reliable forecasting. As Jarvis (1993, p. 121) stated, "A major disadvantage of a top-down model is that predictions cannot be made safely outside the range of the variables encountered in the derivation of the lumped parameter function."

Many studies (e.g., Wright *et al.*, 1993; Root, 1994; Harte *et al.*, 1995) provide examples of a refined approach to analyzing across large and small scales, which Root and Schneider (1995) labeled strategic cyclical scaling. This method builds on the combined techniques in which top-down and bottom-up approaches are applied cyclically in a strategic design that addresses a practical problem: in our context, the ecological consequences of global climatic change. Large-scale associations are used to focus small-scale investigations; this helps ensure that tested causal mechanisms are generating the large-scale relations. Such mechanisms become the laws that allow more credible forecasts of the consequences of global-change disturbances. Levin (1993) observed:

Although it is well understood that correlations are no substitute for mechanistic understanding of relationships, correlations can play an invaluable role in suggesting candidate mechanisms for (small-scale) investigation (p. 14)

Strategic cyclical scaling, however, is intended not only as a two-step process but also as a continuous cycling process between large- and small-scale studies, with each successive investigation building on previous insights from all scales. This approach is designed to enhance the credibility of the overall assessment process, which is why strategic is the first word in strategic cyclical scaling.

If the rate at which humans are injecting greenhouse gases into the atmosphere is not greatly decreased, Earth's climate will most likely warm by several degrees Celsius by 2050. With this in mind, Root (1988a, 1988b) examined the biogeographic patterns of all wintering North American birds. Root chose this group of species because birds are important parts of ecosystems and because of the availability of the necessary data. The National Audubon Society and the US Geological Survey have volunteer forces amassed to aid in the collection of Christmas Bird Count data and Breeding Bird Survey data, respectively. Using Christmas Bird Count data, Root determined that for a large proportion of species average distribution and abundance patterns are associated with various environmental factors (e.g., the northern range limits

of some species are apparently limited by average minimum January temperature; Root (1988a, 1988b)).

The following is the scaling question: What mechanisms (such as competition or thermal stress) at small scales may have given rise to the large-scale associations? Root first tested the hypothesis that local physiological constraints may be causing most of the particular large-scale, temperature-range boundary associations. She used published small-scale studies on the wintering physiology of key species to determine that about half of the songbird species wintering in North America extend their ranges no farther north than the regions where, to avoid hypothermia during winter nights, they need not increase their metabolic rates more than approximately 2.5 times their basal metabolic rate (Root, 1988b). Root embarked on a larger, regional study to determine whether the longer nights – hence, fewer hours of daylight available for foraging – or the colder temperatures in the more northerly locations are relatively more important. Preliminary results indicate that changing temperatures are more likely than day length to explain this effect (Root, unpublished data): thus, global temperature changes would probably cause a rapid range and abundance shift, at least by selected bird species. Indeed, Root found significant year-to-year shifts in ranges and abundances; these shifts are apparently associated with year-to-year changes in winter temperatures. This example permits a clear demonstration of refined methods for cycling across scales to estimate ecological responses to climatic change.

Three-Way Linkages and Community Ecology

The anticipated changes in plant ranges will probably have dramatic effects on animals, both on the large biogeographic scale and on the local regional scale. The ranges of many animals are strongly linked to vegetation. For example, red-cockaded woodpeckers are endemic to mature longleaf pine and pine-oak forests (Csuti, 1988), and the winter range of Sprague's pipit is coincident with bluestem, a grass (Root, 1988c). Consequently, the ranges of various animals that rely on specific vegetation will change as the ranges of these plants shift, assuming that some other factor is not limiting them. If the climate changes more rapidly than the dispersal rates of the plants, it could result in contraction of plant ranges due to die-offs in the south or downslope before individuals can disperse and become established in the north or upslope. Thus, the ranges of animals relying on these plants could also become compressed, and in some instances both the plants and the animals could become extinct. For instance, the red-cockaded woodpecker needs mature, living trees for nesting sites (Csuti, 1988), and if increasing temperature causes most large trees to die before the newly established dispersing trees mature enough, then this woodpecker, federally listed as endangered, could easily become extinct.

Many animal species have ranges that are not directly limited by vegetation but are instead restricted by temperature. This is true for most ectotherms (insects and related arthropods, amphibians, and reptiles) as well as some endotherms (fish, mammals, and birds). For example, the eastern phoebe, a North American songbird, winters in the US in areas with average minimum temperatures warmer than -4°C (Root,

1988b). As the Earth warms, those species directly limited by temperature will be able to expand northward as rapidly as their dispersal mechanisms will allow, again assuming other factors are not limiting them. The animals limited by vegetation will be able to expand their ranges only as rapidly as the vegetation changes. Consequently, the potential for significant disruption among communities is high. For instance, some animals may no longer be able to coexist because an invading species disrupts the balance between competing species or between predator and prey. Therefore, to understand the ecological consequences of global climatic change on animals, the three-way linkages among animals, plants, and climate must be understood. It is critical to realize that this is not simply a one-way process whereby climate influences biota but rather a three-way process because animals and plants affect each other and are affected by climate. At the same time, altered surface vegetation can affect climate because mid-continental summer precipitation is significantly influenced by water vapor from evapotranspiration (Salati and Nobre, 1991).

Climate Forecasts, Ecosystem Responses, and Synergistic Effects

Improve Regional Analysis, Study Transients, and Include Many Variables

The most reliable projections from climatic models are for global-scale temperature changes. Ecological impact assessments, however, need time-evolving (transient) scenarios of regional to local-scale climate changes: included are changes in precipitation; severe storm intensity, frequency, and duration; drought frequency, intensity, and duration; soil moisture; frost-free days; intense heat waves; ocean currents; upwelling zones; near-ground ozone; forest canopy humidity; and ultraviolet radiation and total solar radiation reaching the surface, where photosynthesis is important. Data gathered at many scales and by coordinated volunteer and professional sources are needed for archives of these regional and local variables, which in turn can be used to develop and test models or other techniques for climatic forecasting.

Abrupt Climatic Changes

We have argued that sustained globally averaged rates of Earth and ocean surface temperature changes from the past Ice Age to the present were about 1°C per 1000 years. Alarming, this is a factor of approximately 10 slower than the expected changes of several degrees Celsius per 100 years typically projected for the twenty-first century due to human effects. We emphasize the words sustained globally averaged because comparably rapid regional variations have occurred. For example, about 13,000 years ago, after warm-weather fauna had returned to northern Europe and the North Atlantic, there was a dramatic return to Ice Age-like conditions in less than 100 years. This Younger Dryas miniglacial lasted about 1000 years before the stable recent period was established. The Younger Dryas was also accompanied by dramatic disturbances to plants and animals in the North Atlantic and Europe

(Ruddiman and McIntyre, 1981). During the same period, dramatic shifts can be found outside of the North Atlantic region, but no significant climate change is evident in Antarctic ice cores. However, studies of fossils in the North Atlantic show that the warm gulf stream current deviated many degrees of latitude to the south and that the overall structure of deep-ocean circulation may have returned to near Ice Age form in only decades – a weakening of the vertical circulation known as the conveyor-belt current (Broecker *et al.*, 1985).

Plausible speculations about the cause of the Younger Dryas center on the injection of fresh melt water into the North Atlantic presumably associated with the breakdown of the North American ice sheet (Boyle and Weaver, 1994). Could such a rapid change to the conveyor-belt current be induced today by pushing the present climatic system with human disturbances such as greenhouse gases or sulfur oxides? The potential for this is speculative, of course, but its possibility has concerned many scientists (Broecker, 1998; Rahmstorf, 1999). The prospect of climatic surprises in general is chilling enough to lend considerable urgency to the need to speed up the rate of our understanding, slow down the rates at which we are forcing nature to change, or both.

Adaptability

Our current inability to credibly predict time-evolving regional climatic changes has many implications, one of which concerns the adaptability of agricultural ecosystems, that is, any experience farmers might have with anomalous weather in, for example, the 2020s may not help them adapt to the evolving climate change in the 2030s because a transient climate change could differ dramatically over time. This would inhibit learning by doing, creating a potential lack of adaptability associated with the difficulty of reliably predicting regional climatic consequences (Schneider *et al.*, 2000). Such rapid climate changes would be especially difficult for natural ecosystems to adapt to because habitats do not have the luxury of choosing to plant new seeds or change irrigation systems, soil tillage practices, or other agricultural practices.

Ecological Applications-Driven Climatic Research

Regional projections of climatic change arising from a variety of greenhouse gas and sulfur oxide emissions scenarios are essential for ecological applications. Such studies must stress the climatic variables most likely to have significant effects on biological resources. For example, extreme variability measures, such as high temperature and low relative humidity, are important for evaluating the risk of forest fires (Torn and Fried, 1992; Westerling *et al.*, 2006). Identifying such variables of ecological importance and communicating this information to climate scientists require close interdisciplinary, multi-institutional, and cross-scale research efforts to ensure that combinations of variables relevant to ecological applications receive research priority by climatologists. A focus of climate research toward changing climatic variability (Folland *et al.*, 2002) and extremes (Parmesan *et al.*, 2000) might be

more useful for ecological impact assessments than the current focus among climatic modelers on climatic means.

Interactive, Multiscale, Ecological Studies Needed

Most ecological studies project the response of one species at small scales or shifts in biomes at large scales to an equilibrium, CO₂-doubled climate model (e.g., the *Vegetation/Ecosystem Modeling and Analysis Project*, 1995; Stralburg *et al.*, 2009). What is needed for more realistic and useful ecological impact assessments is a multiscale, multispecies, multitaxa analysis driven by regionally specific, transient climatic change forecasts. The construction of ecological forecasts models first requires long-term, large-scale data sets gathered locally by professional (e.g., US Geological Survey landcover data sets) and volunteer (e.g., National Audubon Society Christmas Bird Count) workers. Without such data sets, virtually no credible progress is possible in determining large-scale patterns of associations among ecological and climatic variables. Small-scale studies informed by large-scale patterns are then needed to refine causal mechanisms underlying such large-scale associations, thereby testing the formulas used to make projections of various species or biome responses to hypothesized global changes. For example, Pacala and Hurtt (1993) suggested small- to medium-scale experiments to improve forest gap models. Their criticisms suggest that largely first principles, bottom-up models may still be unrealistic if some top-down parameters (i.e., growth-modifying functions in the instance of gap models) are not appropriately derived from data at the scale at which the models are being applied (Root and Schneider, 1995).

One obvious truism emerges: Credible modeling required for forecasting across many scales and for complex interacting systems is a formidable task requiring repeated testing of many approaches. Nevertheless, tractable improvements in refining combined top-down and bottom-up techniques can be made. It will, however, take more than one cycle of interactions to reliably address the cross-scale and multicomponent problems of ecological assessment – what we (Root and Schneider, 1995) have labeled strategic cyclical scaling.

Glossary

Advective precipitation When moist air passes over cool ground by advection (wind) and is cooled.

Biodiversity hotspot An area with exceptionally high biodiversity but threatened by habitat loss.

Endemic A species restricted to one place only.

Niche The function of a particular species in an ecological community.

Orographic cloud layer Clouds that are formed as moist air rises over mountains.

Phenology The timing of seasonal activities such as timing of flowering, migration, or breeding.

Stochastic event A random event such as a hurricane or wildfire.

Climate change is predicted to result in a worldwide loss of biodiversity, with extinctions becoming increasingly common in the future. The climate is changing at an ever more rapid rate, affecting individuals and populations and disrupting community interactions and ecosystem functions. Climate change will likely reduce worldwide biodiversity through negative effects on already extinction-prone species such as endemics and those at the top of the food chain. This will likely result in a more homogeneous fauna and flora worldwide that is dominated by generalist taxa that are able to adapt to changing environmental conditions.

Climate Change

Worldwide, the climate is changing at an unprecedented rapid rate. In general, many regions have become warmer and wetter than in the past. Average temperatures have already risen approximately 0.74 °C globally, and the Intergovernmental Panel on Climate Change (IPCC, 2007) reports that recent trends are greater than those of the IPCC 2001 report (0.6 °C). Temperature increases are currently tracking the “worst case scenario” predicted by the (IPCC, 2007), which predicts further increases of between 1.8 °C and 4.0 °C by the end of this century. There has been an increase in the number of heat waves around the world, along with warming of the oceans, coral-bleaching events, retreating glaciers and sea ice, fewer frosts, and heavier rainfall events. The sea level has risen an average of 3.1 mm yr⁻¹ since 1993, and the IPCC predicts a further rise of 0.18–0.59 cm by 2100. Severe weather and catastrophic events are also becoming more common, including El Niño, droughts, floods, and wildfires. Climatic changes are attributed due to increased greenhouse gas (GHG) emissions such as carbon dioxide. Human GHG emissions continue to increase, with an increase of 70% between 1970 and 2005 (IPCC, 2007), due to human activities including the use of coal, oil, and gas for energy and also the burning and conversion of forests for other land uses (IPCC, 2007).

Over history, Earth has experienced much climatic variability, but current climatic changes differ in two important ways in terms of their negative impact on biodiversity and extinction rates. First, the rate of temperature change in the

late 20th century, and that predicted in the near future, is generally considered to be unparalleled in the past 10,000 years. Second, many of Earth's ecosystems are already stressed by other detrimental human impacts, such as land clearing and habitat fragmentation, resulting in small and isolated animal populations that are highly susceptible to the types of stochastic events that climate change will bring. Climate change is predicted to have a profound effect on individuals and populations in animal communities, and its effect on biodiversity and ecosystem function is of worldwide interest and concern.

Extinction Risk

Intrinsic Risks

The risk of extinction is rarely random across species as particular traits make some species more extinction-prone than others (McKinney, 1997). A number of life history traits appear to consistently predispose species to a high risk of extinction across animal groups, especially those associated with a slow life history, including large body size, a long life span, slow maturity, few reproductive events, and the production of a few slow-growing offspring at each reproductive event. These traits, such as low fecundity, mean populations will be slow to recover if reduced to small sizes and therefore more likely to go extinct if a stochastic event increases the rate of mortality (Bennett and Owens, 1997). Larger species are also commonly at the top of the food chain, such as large carnivores, and are predicted to be at high risk of extinction as they are more vulnerable to the cumulative effects of disturbance to species lower down the food chain – so-called chains of extinction (Figure 1).

Other intrinsic factors that have been related to extinction risk include population isolation, such as the populations of endemic species restricted to islands or mountaintops, and ecological specialization, including specialized diet and habitat requirements. Population models also generally predict that there will be an increased extinction risk in populations that show high variability in growth and dynamics, because if a population commonly experiences large fluctuations in size and a stochastic event occurs at a time when that population

Figure 1 A simplified forest food web demonstrating how loss of biodiversity differs, depending on where a species lies in the food chain. Many of the traits that make species vulnerable to extinction tend to increase up the food chain, culminating at the top predator.

Figure 2 A graphical illustration of how population variability can influence extinction risk. This population undergoes great variability in numbers (N) over time; if a stochastic weather event such as a severe flood occurs at a population low, then the population will be unable to recover and will likely go extinct.

is experiencing a crash, extinction is a likely outcome (Figure 2). Poor dispersal ability has also been related to increased extinction risk in a variety of taxa such as insects and frogs. The dispersal ability of such species may have evolved under a less-fragmented landscape structure, and thus individuals emigrating from habitat fragments in search of new suitable habitat patches may be unable to cross nonhabitable areas.

Extrinsic Risks

There are also many extrinsic factors that can contribute to the extinction or decline of a species. Susceptibility to disease is an important determinant in extinction risk, and disease has been implicated as a primary factor in the decline and extinction of amphibians worldwide. Introduced species have also been implicated in the extinction and decline of a variety of taxa in recent years. In Australia, the cane toad (*Bufo marinus*) is toxic to predators such as native cats and snakes and may compete with native amphibians for resources. Anthropogenic activities that currently threaten numerous species include habitat modification, habitat destruction and pollution, overfishing and hunting. These extrinsic risks commonly interact with intrinsic factors to increase extinction risk in the most vulnerable species (Figure 3).

Climate Change, Extinctions, and Biodiversity Loss

Geographic and Landscape Scale Variation in Expected Biodiversity Loss

The degree of climatic change, and also the impact of climate change on biodiversity, is predicted to differ both at a large geographic scale and also at smaller scales such as across altitudinal and vegetation zones. However, data from 75 studies to date that show significant change in biological and physical systems – nearly 90% are consistent with changes expected as a response to warming. Land areas have warmed faster than oceans, and the largest increases in temperature are found at higher northern latitudes, suggesting that terrestrial species at higher latitudes will be most at risk of extinction (IPCC, 2007). However, due to rising sea levels and flooding events, species inhabiting coastal wetland habitats are expected to be at extremely high risk; the IPCC predicts that approximately 33% of coastal wetlands could become open ocean by 2080. Rainfall is projected to increase at high latitudes and also across the equatorial zone but decrease in the subtropics. Although areas at high latitude are predicted to experience greater climatic change in terms of increases in mean annual temperature, the high biodiversity and high proportion of endemic species found in tropical areas mean that even small changes in the tropics could be catastrophic for global biodiversity.

Conservation International recognizes 34 international hotspots of biodiversity – areas across the globe that support generally high species richness and diversity and also high levels of endemism. These areas, although covering only 2.3% of Earth's land surface, are estimated to account for 77% of world's vertebrate biodiversity. Any negative effects of climate change on these areas would thus be extremely detrimental to global biodiversity as a whole. Malcolm *et al.* (2006) modeled extinctions of endemic species from biodiversity hotspots under predicted climatic changes and found an average of 11.6% extinctions in 100 years – vulnerable hotspots were distributed across a variety of biomes, including Mediterranean, tropical, and dry savanna areas. In tropical regions, extinctions induced by climate change exceeded those predicted

through deforestation. Tropical areas account for a disproportionate number of hotspot areas (54%), and tropical montane cloud forest (high altitude forest with persistent cloud and mist) is particularly important in terms of biodiversity and endemic species. However, tropical mountain systems, and especially tropical montane cloud forests, are likely to be extremely vulnerable to climatic changes due to their unique and fragmentary nature and association with elevational and temperature gradients. The possible effects of climate change on tropical mountain areas include a general increase in temperature, increased water loss through evaporation, a rise in the average basal altitude of the orographic cloud layer, changing rainfall input, decreased soil moisture, increases in fire and drought, and increased invasion potential for introduced pest species. Furthermore, forest types at high elevation have been shown by to be more vulnerable to climate change than other tropical forest types (Enquist, 2002), possibly due to the lower migration rates found in tropical plant species compared to those in boreal or temperate areas, as demonstrated by Jay Malcolm and co-workers.

Figure 3 Projected change in the relative population size and distribution area of rainforest birds following altitudinal range shifts associated with climate warming. The relationship is linear where population size declines in direct proportion to distribution area (i.e., dotted gray line) and curvilinear where population size declines more rapidly (below the dotted gray line) or more slowly (above the dotted gray line) than distribution area with increasing temperature. Number labels refer to individual species of rainforest birds: (1) Macleay's honeyeater (*Xanthotis macleayana*); (2) tooth-billed bowerbird (*Scenopoeetes dentirostris*); (3) pied monarch (*Arses kaupii*); (4) Victoria's riflebird (*Ptiloris victoriae*); (5) golden bowerbird (*Prionodura newtoniana*); (6) chowchilla (*Orthonyx spaldingii*); (7) mountain thornbill (*Acanthiza katherina*); (8) fern wren (*Oreoscopus gutturalis*); (9) Atherton scrub wren (*Sericornis kerii*); (10) bridled honeyeater (*Lichenostomus frenatus*); (11) gray-headed robin (*Heteromyias albispectularis*); (12) Bower's shrike-thrush (*Colluricincla boweri*).

Effects of Climate Change on Individuals And Populations

Research over the past decade has demonstrated that many of the intrinsic and extrinsic factors that are related to extinction risk within a species can be affected by climate change. The observed impacts of climate change on individuals and populations are increasing rapidly, although the magnitude and direction of effects appear to vary considerably between species. The most commonly observed impact is shifts in distribution and range of animals and plants; the most common pattern has been shifting toward the poles for terrestrial and marine species and also higher in altitude for mountain species. These shifts have resulted in range expansions for some species but contractions for others. A key review by Chris Thomas and colleagues was among the first to show range retractions are occurring as a result of climate change, highlighting research conducted on 16 butterfly species in Spain by Robert Wilson and co-workers, who document that range boundaries have risen by an average of 212 m in the past 30 years, accompanying a 1.3 °C rise in mean annual temperature. More recently, Chen *et al.* (2011) estimate, using a meta-analysis approach, that species are moving up a median of 11 m in altitude per decade and to higher latitudes at 11 km per decade; these rates are around two and three times greater than earlier predictions. Furthermore, Shoo *et al.* (2005) incorporated spatial patterns of abundance into a predictive model and demonstrate that for many endemic wet tropics birds in Australia, as temperature increases population size is likely to decline more rapidly than distribution area (Figure 4). This means that extinction risk associated with climate change will be more severe than expected from decline in distribution area alone.

Recently, mass deaths of individuals as a result of extreme weather events, particularly heat waves, have also been noted in a variety of species and locations. In Australia, more than 3500 flying foxes were seen to perish when temperatures rose to over 42 °C (Welbergen *et al.*, 2008). Heat-related deaths

Figure 4 A graphical representation demonstrating how different responses to climate change can result in the decoupling of predator-prey relationships. In this case, as the climate has changed over time, breeding of a predator (for instance, a migratory bird) is occurring earlier in the year. The peak food abundance of the predators main prey (for example, caterpillars) has also shifted to earlier in the year – but not to the same degree. Over time, this has resulted in an increasing mismatch between predator food requirements for breeding and prey biomass availability, likely resulting in breeding failures for the predator.

have also been noted in birds and are expected to rise as heat waves become more common (McKechnie and Wolf, 2010). For restricted species, a mass die-off event could result in local or total extinction. Ocean warming has also resulted in mass coral-bleaching events; a study by Carpeneter *et al.* (2008) predicts that one-third of reef building corals are threatened with extinction primarily as a result of climate change.

Shifts in phenology and variations in reproductive behavior and success have also been documented for a variety of taxa. For example, many migratory birds are arriving at their breeding grounds earlier and reproducing earlier (Van Buskirk *et al.*, 2009); the impacts on reproductive success appear mixed, with both positive and negative outcomes (Møller *et al.*, 2010). Research suggests shifts in the timing of reproduction may often be in response to changes in food availability as climate change affects species further down the food chain. For example, Jaume Forcada and co-workers show that pup production in Antarctic fur seals, South Georgia, has declined considerably since 1985 with increased sea surface temperatures, likely associated with low availability of food (krill). A negative effect of climatic warming on reproductive parameters is also the likely cause of extinction in endemic Costa Rican amphibians such as the golden toad (*Bufo periglones*). Crump *et al.* (1992) hypothesized that climatic changes, specifically warmer water temperatures and less-advective precipitation, created adverse breeding conditions for the toads. These species also displayed many of the traits purported to predispose species to high extinction risk, in particular restricted distributions: the golden toad was found only in an area ~0.5 km by 8 km and elevations between 1500–1620 m. Global warming is accompanied by an increase in ambient ultraviolet b (UV-B) radiation, and Michael J. Adams and colleagues have shown that a north temperate frog species, *Rana cascadae*, chooses breeding sites with low UV-B attenuation; it is likely that high UV-B exposure results in lower survival and high deformity in offspring.

Finally, there is also evidence that climatic changes have resulted in significant changes in body mass and size in a number of vertebrates. According to Bergmann's rule, animals in warmer areas should be smaller than those in cooler areas, as the relatively smaller body surface of larger animals may assist in heat conservation in cooler climates. Thus, we might predict a decrease in body size or mass or both with global warming. A number of authors have shown that this is indeed the case for a number of species, including plants, birds, and mammals (review in Sheridan and Bickford, 2011). Decline in size and mass within a species have strong implications for other life history traits and extinction risk and reduced size may negatively impact on reproductive success and survival. However, contrary to the predictions of Bergmann's rule, the converse pattern has also been found in lizards and mammals, particularly in very cold areas. In isolated populations of the common lizard (*Lacerta vivipara*) in the French Alps, an increase in temperatures resulted in an increase in body size, with an associated increase in reproductive success (clutch size and reproductive output) (Chamaille-Jammes *et al.*, 2006). Similarly, Yorav and Jonathan Yom-Tov demonstrate an increase body mass in masked shrews in Alaska. In these environments with extreme winters, global warming may have resulted in an increase in food availability in these

insectivorous species or allowed them a longer growth period – resulting in size or mass increases that may benefit these species, at least in the short term.

Effects of Climate Change on Communities and Ecosystems

As the previous section highlights, the response of different species to climate change varies considerably, which may disrupt the coupling between species, with cascading effects up the food chain resulting in extinctions and biodiversity loss. For example, the fecundity and reproductive success of one species is commonly dependent on the abundance and survival of their food source, such that timing of births usually coincides with peak food availability. An important concept in the effort to predict biotic responses to climate change is the *temporal match–mismatch* (TMM) hypothesis, which suggests that climate change can create a mismatch between timing of peak breeding of predator and prey (Figure 4). Studies indicate that trophic mismatch is already occurring. For example, mistiming of avian reproduction and caterpillar biomass appears to be relatively widespread and has resulted in failed breeding and population crashes in many birds (reviewed in Visser and Both, 2005), and mismatch between plants and pollinators have also been noted (Hegland *et al.*, 2009). The decoupling of phenological relationships between species within a community will have important implications for trophic interactions, leading to changes in food-web structure and ecosystem-level changes. Other recent empirical studies highlight the potential for climate change to affect keystone predators, with impacts throughout the food chain and effects touching community structure and diversity (Harley, 2011).

A number of authors have also demonstrated that extreme weather events, predicted to become more common as climate change progresses, and general global warming can result in changes to species assemblages and community structure through differential effects on species. Following Hurricane Georges, which hit the Caribbean in 1998, there was a decline in abundance and species richness in bat communities, with large species more affected than smaller species, and frugivorous and nectarivorous species more affected than insectivorous species (Jones *et al.*, 2001). Similarly, following Hurricane Isis in 1998, there was a change in the composition of cloud forest birds in Mexico, whereby generalists were favored following the storm (Tejeda-Cruz and Sutherland, 2005). In Australia, Luke Shoo and colleagues predict that 74% of rainforest birds in the wet tropics will become threatened as a result of projected warming in the next 100 years. However, extinction risk varies according to where on the altitudinal gradient a species is currently most abundant. Upland birds are predicted to be most affected and are likely to be immediately threatened by small increases in temperature, whereas there may be a capacity for the population size of lowland species to increase, at least in the short term. Plant communities are likely to be similarly affected – Nadlini Nadkarni and Rodrigo Solanao demonstrate that climate change will result in negative effects on the productivity and longevity of rainforest epiphytes in tropical cloud forest in Costa Rica, resulting in subsequent emergence of terrestrial components into the canopy community.

Interactions of Climate Change and Existing Risk of Extinction

For many species, it is likely that the factors that underlie their existing risk of extinction will be exacerbated by climate change. For example, climate change may increase the occurrence, range, or prevalence of diseases, parasites, and other introduced pest species (reviewed by Brook *et al.*, 2008). The chytrid fungus, *Batrachochytrium dendrobatidis*, has been implicated in widespread amphibian extinctions. Evidence suggests that large-scale warming exacerbates outbreaks of chytrid fungus by producing conditions optimal for the growth of the fungus (Pounds *et al.*, 2006). Further evidence that warming can expand the range of pest species comes from North America, where the aggressive mountain pine beetle, *Dendroctonus ponderosae*, has expanded its natural range and now occupies areas naïve to this species. Cudmore *et al.* (2010) demonstrate that reproductive success for the beetles is higher in areas that have not seen previous outbreaks of the pest; this increased beetle productivity is likely responsible for massive tree death in affected areas.

Endemic species commonly display many traits that predispose them to high extinction risk, including small geographical ranges, specific ecological requirements, and little capacity for long-distance migration. Thus, the already intrinsically high extinction risk for endemic species is also expected to increase as the climate changes. For example, Thomas *et al.* (2004) demonstrate a strong negative relationship between geographical range size and risk of extinction under predicted climate-warming scenarios. They found that 15–37% of species in their data set will be “committed to extinction” by 2050, the majority being species with already small geographic range sizes. More recently, Isaac *et al.* (2008) demonstrate that the endemic species of Australia’s wet tropics have both lower resistance (the ability of species to withstand an environmental perturbation) and lower resilience (ability to recover from an environmental change); this means these species are at greater risk of extinction under climate change, and other environmental change, than more widespread, generalist species.

Conclusions

There is no doubt that a changing climate has already had significant impacts on global biodiversity patterns and extinctions and will continue to do so. The research reviewed here indicates that extinctions due to climate change will not be random and that species with more generalist ecological requirements will be better able to cope with and adapt to climatic changes. Those species that display traits that already predispose them to high extinction risk, such as specialists and range-restricted species, will be negatively affected. We will likely see the decline and extinction of many of these species and many more becoming threatened. As generalists are favored and introduced species expand their ranges, we are also likely to see a more homogeneous, less diverse fauna and flora as generalist species become more dominant.

The capacity to adapt to a changing climate will depend on all of the intrinsic and extrinsic factors discussed and the

actual realized degree of climate change. We would suggest that there is not enough time to evolve novel traits and extinction probability will largely depend on existing plasticity in relevant ecological and evolutionary characteristics – with some possibilities for active adaptation management, such as habitat restoration, wildlife corridors, and assisted migration – to help increase resilience. Natural resource management should focus on maintaining ecosystem resilience while putting pressure on governments to reduce emissions. Research effort should focus on the factors discussed in this chapter to allow more robust predictions and better evaluation of the relative extinction proneness of species and ecosystems. This knowledge will enable informed decisions and ensure the efficient and effective allocation of scarce management resources.

Glossary

Climatic models Mathematical descriptions of the flows of energy, momentum, and materials around the atmosphere and oceans, typically run on large computers to stimulate the Earth's climate naturally and when disturbed by greenhouse gases (GHGs) or the other so-called forcings or disturbances.

Global change disturbances Alterations or disturbances to the natural conditions of the global atmosphere (e.g., GHGs produced by human activities) or to enough regions (e.g., large-scale deforestation or the widespread introduction of exotic, invasive species in many places throughout the world) to have global impacts.

Global warming The additional heating of the Earth's climate from the incremental injection of GHGs to the atmosphere from human activities such as deforestation or fossil fuel consumption.

Greenhouse gases Gases in the atmosphere, which selectively let more of the solar energy into and out of the atmosphere than they permit the transmission of long-wave infrared radiation. They contribute to the greenhouse effect, which traps radiant energy in the lower atmosphere and makes the Earth warmer.

Synergisms Interactions among many factors, which collectively may have a much larger or smaller effect than the sum of the effects of each factor acting independently.

Forces Impacting Wild Species

Biological diversity, which includes various species of plants, animals, fungi, and microorganisms, genetic differences within species, and the variety of ecosystems and habitats, is the result of billions of years of evolution shaped by natural processes and, increasingly, by human influences. Humans are an integral part of this web of complex communities interacting with one another and their physical environment, and we are entirely dependent on them for our well-being and survival. This complex, interdependent web of ecosystems either directly or indirectly provides the basic materials for life (e.g., food and water), delivering essential life-support goods and services. The Millennium Ecosystem Assessment (2005) identifies 24 ecosystem services that maintain the essential life-support processes of the planet, including primary production and nutrient recycling, pollination, air and water purification, waste detoxification and decomposition, soil fertility regeneration, protection from natural disasters and disease (e.g., regulating climate, floods, and pests), and production and maintenance of biodiversity. Of the 24 ecosystems, 15 have become endangered over the last 50 years and five more are threatened with disruption. This array of services is generated by a complex interplay of natural cycles powered by solar energy and operating across a wide range of space and time-scales. *Daily (1997)* identifies such ecosystem goods as sea-food, fodder, fuel wood, timber, and pharmaceutical products that are of great importance to human populations as well as an integral part of essential ecosystems that support other

species. Ecosystems also provide the basis for such important aspects of human culture as spiritual needs, knowledge systems, and traditional use. Biodiversity is essential for the sustained provision of these support goods and services that are provided at all levels – local, regional, and global – each one making crucial contributions to human well-being (UNEP, 2005).

Recognizing the fundamental role of biodiversity in supporting human life, the Convention on Biological Diversity (CBD), a legally binding landmark treaty, was opened for signature at the Rio Earth Summit and entered into force in 1993. The CBD's three main objectives are the conservation of biodiversity, the sustainable use of its components, and the fair and equitable sharing of the benefits arising out of the utilization of genetic resources. In 2002, 10 years after the Convention's entry into force, Parties acknowledged that there is a continued threat to biodiversity from human activities, reaffirming that biodiversity is the living foundation for sustainable development, that the rate of loss is still accelerating, that threats must be addressed, and that the Convention continues to be a key tool for sustainable development. At this time, Parties adopted a Strategic Plan whereby they committed to a more effective and coherent implementation of the Convention objectives so as to achieve a significant reduction of the current rate of biodiversity loss at all levels by 2010. There are five main threats to biodiversity, which are commonly recognized in the programs of work of the Convention: habitat change, invasive alien species, climate change, nutrient loading and pollution, and overexploitation. These work synergistically together to amplify negative impacts on wild species.

[†]Deceased.

Threats to Biodiversity: Habitat Change, Invasive Species, Overexploitation, Pollution, and Nutrient Loading

Human activities are responsible for much of the accelerating loss of biodiversity. Humans are adversely impacting biodiversity by changing habitat, generating pollution, and loading nutrients into the natural environment, introducing invasive species, overharvesting species, and affecting climate.

Habitat Change

The natural landscape has been divided or fragmented for urban and suburban development and agricultural production disrupting interactions among organisms and destroying, reducing, or seriously altering essential habitats. Habitat fragmentation not only affects species, but also affects the processes that drive biodiversity. Fragmentation of habitat causes large populations to be broken into smaller populations that may be isolated from one another. Eventually, loss of habitat can affect the genetic variability and viability of populations that can lead to local extinctions. If local extinction of species occurs, fragmentation cuts off the potential for repopulation because no intact populations are nearby. If a species experiences local extinction in many locations, this can eventually lead to global or permanent extinction. Maintaining habitat is important for annual animal migrations. For example, the Mississippi River, which crosses through the Midwest, serves as a main flyway for neotropical migrating birds. If the habitat that these birds require at stopover sites, where they replenish their energy along their migration route, are significantly degraded, the species are in jeopardy of not having enough energy to complete their trip.

Poor agricultural practices degrade soil quality and promote the loss of topsoil. Furthermore, agriculture has resulted in local reductions and extirpations of flora and fauna associated with agricultural lands (e.g., grassland and scrubland plants, birds, and wild pollinating insects).

Overharvesting/Overexploitation

Overharvesting has a great effect on biodiversity and often occurs with habitat loss, as removal of an organism from its environment can have irreversible impacts on the environment itself. Humans have historically exploited plant and animal species to maximize short-term profit, at the expense of sustainability of the species or population. The unsustainability of biological-resource extraction is rooted in three main problems:

1. too many people who want the resource,
2. short-term return on investment goals of extractors, and
3. lack of information about the ecology and life histories of populations being harvested.

Overexploitation follows a predictable pattern: initially, a species harvested from the wild can provide a substantial profit, which encourages more extraction and leads to the development of more large-scale and cost-effective methods of harvesting the species, which eventually depletes the resource. Quota systems are often put in place, leading to more competition, decreased earnings and the need for government subsidies to support the extraction industry. The fishing industry, the logging industry, and grazing of cattle on public

lands have all been examples of this process of over-exploitation. When the rate of increase in demand for the resource far outstrips the reproductive rate of the population, demand outstrips supply, and drives the value of that resource higher, increasing the incentive to extract the resource, and eventually leading to the collapse of the population. The results for the resource are population crashes, which can ultimately lead to global extinction.

Pollution and Nutrient Loading

Human activities produce pollution, which adversely affects ecosystems. Human-generated pollution impacts water resources in the form of toxic discharges of metals, organic chemicals, and suspended sediments usually found in industrial and municipal effluents, which can inversely impact the biota (living organisms) in an ecosystem; bacterial contamination from human waste that can cause disease; and nutrient buildup of, for example, phosphorus and nitrogen that often originate as runoff from fertilizers applied on agricultural fields. Nutrient loading can result in excesses that stimulate rapid growth of algae and aquatic plants, ultimately limiting the amount of oxygen and light available to other organisms in the ecosystem.

Air pollution generated by human activities causes significant damage to ecological resources by directly damaging plants, acidifying lakes, streams, and soil, and leading to concentrations of poisons in the food chain. Acid precipitation, usually caused by sulfur dioxide and nitrogen dioxide combining with moisture in the air, is extremely harmful to terrestrial plants as well as organisms that live in rivers and lakes. Such pollution directly affects crops. Ground-level ozone over time reduces plant growth and fruit production and renders plants more vulnerable to disease and insect attack. Particulate matter can stunt plant growth by scattering the Sun's rays and reducing sunlight.

Introduction of Exotic Species

Exotic species are organisms that have been introduced into an area outside their normal distribution. Human individuals or agencies have both intentionally or accidentally introduced alien species into ecosystems, sometimes with devastating unintended consequences. The presence of such species can alter habitat, profoundly affect food chains with the introduction of new predators, affect the ability of native species to compete for food and habitat acquisition due to the lack of local controls (disease and predators) to keep populations of exotic species in check, promote hybridization – the interbreeding of native and nonnative species – resulting in the decline and extinction of native species, and introduce pest species that can cause disease or parasitic infestations. These impacts all combine to impact biodiversity by decreasing the number of native species, thus causing regional homogenization of ecosystems.

Climate

Scientists have documented the important role that climate plays in the geographic distribution of the world's ecosystems. Climate variability and change can affect plants and animals

in a number of ways, including their distributions, population sizes, physical structure, metabolism, and behavior. The Earth's climate is vastly different now from what it was 100 million years ago when dinosaurs roamed about the planet and tropical plants thrived closer to the poles. It is different from what it was 20,000 years ago when ice sheets covered much of the Northern Hemisphere. Although the Earth's climate will surely continue to change, climatic changes in the distant past were driven by natural causes, such as variations in the Earth's orbit, sunspots or volcanic eruptions. In 2007, the IPCC reported that the warming of our climate is unequivocal and that this increased warming is very likely due to human-caused increases in GHGs (Intergovernmental Panel on Climate Change (IPCC), 2007a). Current and future climatic changes thus have an additional source of change – human activities. Many activities associated with human economic development have changed our physical and chemical environment in ways that modify natural resources. These include activities that burn fossil fuels that release CO₂, use land for agriculture, or urbanization that causes deforestation. We are already feeling the climatic effects of having polluted the atmosphere with GHGs such as CO₂. Humans cannot directly rival the power of natural forces driving the climate – for example, the immense energy input to the Earth from the Sun that powers the climate. We can, however, indirectly alter the natural flows of energy enough to create significant climatic changes. The atmosphere has a natural capacity to trap radiant heat near the Earth's surface – the so-called greenhouse effect. This natural phenomenon acts as an atmospheric blanket, allowing solar energy to warm the climate by trapping long-wavelength radiant energy called terrestrial infrared radiation near the Earth's surface. The natural greenhouse effect is responsible for ~33 °C (60 °F) of surface warming. But, human-induced emissions of GHGs are inadvertently modifying the climate by enhancing the natural greenhouse effect, and are projected to result in a global warming of 1.1–6.4 °C or higher in the twenty-first century (Intergovernmental Panel on Climate Change (IPCC), 2007a). Such an increase in global mean temperature, even at the lower end of the range, will likely result in ecologically significant changes, which is why climatic considerations are fundamental in the discussion of the status and trends of ecological conditions. Quantitative evaluations of the potential effect of human activities in creating global change are needed. Such evaluations are also central to potential policy responses to mitigate global changes (Schneider, 1997; Root and Schneider, 2005; Intergovernmental Panel on Climate Change (IPCC), 2001c, 2007c).

Synergisms

With continued and more severe changes in the climate, the ability of wildlife to adapt through migration and physiological change will be increasingly limited. The challenge is even greater when considered along with the broad range of other environmental threats currently affecting wildlife, such as habitat fragmentation and loss, environmental contamination, and invasive species. People fragment natural habitats for farmland, settlements, mines, roads or other

developmental activities. As the climate changes, individual species of plants and animals will be forced to adjust if they can, as they have in the past. It seems unlikely that all of the migrating species that survived the Ice Age would be able to safely reach refuges by migrating across the freeways, agricultural zones, industrial parks, and cities of the twenty-first century. An additional complication arises with the imposition of the direct effects of changes in CO₂, which can change terrestrial, freshwater, and marine primary productivity, drop the pH of the oceans significantly, and alter the competitive relations among photosynthesizing organisms and among plants and animals.

One representative instance of synergism is that of the woodland caribou (Boutin *et al.*, 2011). This species is restricted to large undisturbed tracks of Boreal Forest. As humans invade the Boreal Forest, land-use changes have forced a contraction of the caribou's current range to about half the size of the historic range. Now with climate change, there is added concern about the increasing of frequent and severe forest fires. The contraction of the Boreal Forest may be faster than expected due to both human land-use change and severe fires, which in turn will cause the contraction of the range of the woodland caribou. If protection of the Boreal Forest is not implemented, then in the extreme situation this caribou species could face extinction. This potential for extinction indicates how the already high rate of extinctions throughout the world could be exacerbated by climatic changes occurring more rapidly than species can adapt (Pimm *et al.*, 1995, 2006; Pereira *et al.*, 2010; Barnosky *et al.*, 2011). Thomas *et al.* (2004) conclude that despite the many uncertainties that remain in projecting extinctions, "the consistent overall conclusions across analyses establish that anthropogenic climate warming is likely to be the greatest threat in many if not all regions," and that the most severe climate change impacts are likely to result from interactions among threats such as habitat loss, fragmentation, and competition with invasive species.

The synergism question raises a controversial management problem of anticipating global change risk and responding. One such response is setting up interconnected nature reserves or networks of adequate habitat allowing species to move as the need along habitat corridors to ensure against some species becoming extinct due to climatic changes. Alternatively, we could simply let the remnants of relatively immobile wildlife and natural plant communities remain in isolated reserves and parks as they exist now, hoping the species can survive in a steadily warming environment. If we opt for more environmental safeguards by interconnecting our parks and refuges, the question then becomes how we interconnect the nature reserves. The nature of corridors or networks is itself an interesting scientific question, for the network needs to invite species to move to another area but not be of sufficient quality to encourage breeding behavior within the corridor, which could cause populations settling in corridors to become sinks (i.e., not producing enough young to sustain a population) and not serve the purpose of sustaining biodiversity. Priorities must be set and money made available for constructing adequate networks through which species can travel. For example, elevated sections of highways may be needed to allow for migration routes, similar to what was done for the caribou in the Arctic when the Alaskan pipeline was built. To examine

such questions as these in scientific detail, it is first necessary to make a multidisciplinary examination of the sub-components of the various aspects of climatology and ecology. The authors begin with a discussion of climatic history and climate processes important to wild species, followed by a discussion of examples of the interactions between climate and biological systems, particularly the changes in climate induced by human activities. Next, they discuss climate and ecological modeling and validation, focusing on possible synergisms among ecology and climate change. The authors conclude with recommendations for future research.

Climate History: What Has Happened

Scientists can reconstruct the cyclical expansion and contraction of polar caps and other ice masses from ice core samples taken from Greenland and Antarctica. When snow falls on high, cold glaciers, the air trapped between snow grains is eventually transformed into air bubbles as the snow is compressed into ice from the weight of subsequent accumulations. The ratio of two oxygen molecules with different molecular weights (O^{16} and O^{18} isotopes) is a proxy record for the temperature conditions that existed when the snow was deposited. From this, scientists have been able to determine that the ice buildup from 90,000 to 20,000 years ago was quite variable and was followed by a (geologically speaking) fairly rapid 10,000-year transition to the (current) climatically very stable Holocene Period. The Holocene is the 10,000-year warm interglacial period in which human civilization developed and modern plant and animal distributions evolved to their current states (Eddy and Oeschger, 1993). These ice cores also provide information on the presence of CO_2 , an important greenhouse gas. Carbon dioxide as well as methane (CH_4), another greenhouse gas, were in much lower concentrations during cold periods than in interglacials. This implies an amplifying effect, or a positive feedback, because lower amounts of these gases during glacial periods means less-trapped infrared radiative heat, amplifying the cooling, and vice versa during interglacials. The ice cores also show that concentrations of CO_2 and CH_4 and temperature were remarkably constant for about the past 10,000 years (before AD 1700), particularly when compared with longer records. That relative constancy in chemical composition of the atmosphere held until the industrial age of the past two and half centuries.

The transition from Ice Age to the Holocene took 5000–10,000 years, during which time the average global temperature increased 5–7 °C and the sea level rose 100 m. Thus, we estimate that natural rates of warming on a sustained global basis are about 0.5–1 °C per thousand years. Such changes were large enough to have radically influenced where species live and to have potentially contributed to the well-known extinctions of woolly mammoths, sabertooth cats, and enormous salamanders.

A large interdisciplinary team of scientists, including ecologists, palynologists (scientists who study pollen), paleontologists (scientists who study prehistoric life, especially fossils), climatologists, and geologists formed a research consortium (Cooperative Holocene Mapping Project (COHMP), 1988; Wright *et al.*, 1993) to study the dramatic ecological

changes accompanying the transition from Ice Age to the recent interglacial period. One group of these researchers used a variety of proxy indicators to reconstruct vegetation patterns over the past 18,000 years for a significant fraction of the Earth's land areas. In particular, cores of fossil pollen from dozens of sites throughout North America clearly shows how boreal tree pollen, now the dominant pollen type in the boreal zone in central Canada, was a prime pollen type during the last Ice Age (15,000–20,000 years ago) in what are now the mixed hardwood and Corn Belt regions of the US. During the last Ice Age, most of Canada was under ice; pollen cores indicate that as the ice receded, boreal trees moved northward chasing the ice cap. One interpretation of this information was that biological communities moved intact with a changing climate. In fact, Darwin (1859) asserted as much.

"As the arctic forms moved first southward and afterward backward to the north, in unison with the changing climate, they will not have been exposed during their long migrations to any great diversity of temperature; and as they all migrated in a body together, their mutual relations will not have been much disturbed. Hence, in accordance with the principles inculcated in this volume, these forms will not have been liable to much modification."

If this were true, the principal ecological concern over the prospect of future climate change would be that human land-use patterns might block what had previously been the free-ranging movement of natural communities in response to climate change. The COHMP, however, incorporated multiple pollen types into its analyses, including not only boreal species but also herbs and more arid (xeric) species as well as oaks and other mesic species. They discovered that during the transition from the last Ice Age to the present interglacial, nearly all species moved north, as expected. During a significant portion of the transition period, however, the distribution of pollen types provided no analog or similar associations to today's vegetation communities (Overpeck *et al.*, 1992). Late-Quaternary global warming caused individual species distributions to change along environmental gradients in different directions, at different rates, and over different periods (Graham and Grimm, 1990). That is, whereas all species moved, they did so individual by individual, not as linked groups of species. Consequently, the groupings of species during the transition period were often dissimilar to those present today (Figure 1). Graham and Grimm (1990) observe that in light of the paleoecological record, which reveals that nonanalog climates produce nonanalog assemblages, individualistic changes can be anticipated in the future.

The relevance of this conclusion is that in the future, ecotypes will not necessarily move as a unit as climate changes (assuming there is enough time and space for such a migration). Credible predictions of vegetation changes from climatic changes projected from human activities cannot neglect transient (i.e., time-evolving) dynamics of the ecological system. Furthermore, caution should be exercised against relying too much on past conditions in forecasting future patterns resulting from global change forcings because the forecasted global average rate of temperature increase exceeds those rates typical of the last 120,000 years. Recently, ice core researchers have extended the analyses of the cores back over several glacial/interglacial cycles, finding very similar results to that of

Figure 1 Selected paleovegetation maps reconstructed using the method of modern analogs and more than 13,000 samples of fossils and modern pollen: (a) 18,000 BP, (b) 12,000 BP, (c) 6000 BP, and (d) modern. No vegetation is mapped in areas without fossil pollen data, and no analog refers to vegetation without any modern analog. Data from Overpeck JT, Webb RS, and Webb III T (1992) Mapping eastern North American vegetation change over the past 18,000 years: No analogs and the future. *Geology* 20: 1071–1074.

the past cycle. If, as predicted, the rate of warming caused by the “greenhouse effect” is greater than in past events, then the individualistic responses may be even more profound. Therefore, possible future changes inferred from past changes can be taken only as a guide or a means to verify aspects of the forecasts of models of climate or ecosystem dynamics (Crowley, 1993; Schneider, 1993a, b). Such verification exercises may provide more credible forecasts of the effects of climatic change on animals.

Processes of Climate Change Important to Wild Species

Trends (Over Last 100 Years)

The Earth’s climate system has demonstrably changed on both global and regional scales since the preindustrial era. Key

observed twentieth century changes in the Earth’s atmosphere, climate, and biophysical system include increases in atmospheric concentrations of greenhouse gases (GHGs), global mean temperature, precipitation, extreme weather events, and sea levels as well as diminishing ice, snow cover, and permafrost (Intergovernmental Panel on Climate Change (IPCC), 2001d).

CO₂ has increased ~36% above 1000–1750 levels, methane by ~160%, nitrogen dioxide by ~20%, tropospheric ozone by 35% (varying by region), with increases as well in hydrofluorocarbons (HFCs), and perfluorocarbons (PFCs).

Global mean surface temperature has risen 0.85 °C, with land areas warming more than the oceans. Northern Hemisphere surface temperature increased more during the twentieth century than during any other century in the last 1000 years. The 1990s was the warmest decade of the millennium, and the first decade of the twenty-first century has been even

warmer, with nine of the ten warmest years on record occurring in the twenty-first century. The diurnal temperature range has decreased over the years 1950–2000 over land, and it is probable (with a 66–90% confidence level) that at nighttime minimum temperatures increased at twice the rate of daytime maximum temperatures. Hot days increased whereas cold days decreased. It is very likely that continental precipitation increased by 5–10% over the twentieth century in the Northern Hemisphere, although it decreased in some regions. Heavy precipitation events increased at mid- and high-northern latitudes. Summer drying and associated incidence of drought have likely increased in a few areas, and in some regions including parts of Asia, Australia and Africa, there has been an observed increase in the frequency and intensity of droughts in recent decades.

Global mean sea level increased at an average annual rate of 1–2 mm during the twentieth century. It is very likely that the duration of ice covering rivers and lakes decreased by about 2 weeks over the twentieth century in mid- and high latitudes of the Northern Hemisphere. In September the Arctic sea-ice extent and thickness thinned as much as ~40% in the recent decade when compared to the thickness from 1979 to 2000, according to the National Snow and Ice Data Center. As well, there was a widespread retreat of nonpolar glaciers during the last century. Snow-cover area very likely decreased by 15% since global observations became available from satellites in the 1960s. Permafrost thawed, warmed, and degraded in parts of the polar, subpolar, and mountainous regions. El Niño events became more frequent, persistent, and intense during the last 20–30 years compared with the previous 100 years. Growing seasons lengthened by about 1–5 days per decade during the last 40 years in the Northern Hemisphere, especially at higher latitudes. Plant and animal ranges for many insects, birds, mammals, and fish have shifted poleward and up in elevation. The breeding, flowering, and migration of some plants, birds, and insects have shifted: Certain plant species are flowering earlier, many migrating birds are arriving in their spring locales and breeding earlier, and numerous insects are emerging earlier in the Northern Hemisphere. Coral reef bleaching has increased in frequency, especially during El Niño events.

Global inflation-adjusted weather-related economic losses have risen an order of magnitude over the last 40 years – an observed upward trend, which is linked to both socio economic factors (e.g., population growth, increased wealth, and urbanization in vulnerable areas) as well as to regional climatic factors (e.g., changes in precipitation and flooding events).

Importance of Extremes

Parmesan *et al.* (2000) state that climate drives biotic systems by affecting individual fitness, population dynamics, distribution and abundance of species, and ecosystem structure and function. In the absence of humans, broad-scale, long-term consequences of climatic warming on wild organisms are generally predictable. For example, evidence from Pleistocene glaciations indicates that most species responded ecologically by shifting their ranges poleward and upward in elevation,

rather than through local adaptation (e.g., morphological changes). However, such broad patterns do not reveal the important part that extreme weather events play as mechanistic drivers of broad ecological responses when compared with the effects of gradual climatic trends. Parmesan *et al.* (2000) report evidence of the effects of extreme weather events on shaping the processes of biotic systems. Thus, they must be included in biological models used to project future changes.

With regard to Lepidoptera (butterflies and moths) and birds, extreme weather events appear to drive local population dynamics. Evidence of direct effects of extreme weather events include many Edith Checkerspot butterfly population extinctions associated with particular climatic events such as severe drought over California (Ehrlich *et al.*, 1980; Singer and Ehrlich, 1979; Ehrlich and Hanski, 2004) and extreme winter weather events in the California Sierra Nevada (Singer and Thomas, 1996; Thomas *et al.*, 1996). Two Sierra Nevada weather events produced a low winter snow pack, which triggered an early emergence of adult butterflies well before flowers were in bloom, which led to mass starvation of the adult population. During a third event, temperatures fell to -5°C on 16 June without insulating snowfall, which killed the host plants and led to the starvation of the young caterpillars. Infrequent and severe climatic events, which produced short-term responses at the population level, appear to have driven a gradual range shift in this butterfly species, which has shifted its range northward and upward during the twentieth century. According to Parmesan (1996), this shift is the result of increased population extinctions at its southern-range boundary and at lower elevations, with a symmetrical tendency toward population stability along the northern-range boundary and at the highest elevations.

Migratory bird populations have exhibited a shift in abundances in relation to weather – their abundances are higher at their southern-range areas during cold winters (in which there is an increase in the number of days below a given temperature threshold) and higher at their northern-range areas when the weather is warmer (Root, 1999).

Extreme weather events can also affect morphology, influencing shape, size, and color of individuals (Hadly, 1997). Impacts can affect more than one tropic level in a food web, as has been documented in the case of the seed-feeding finches in the Galapagos Islands, whose populations are dependent on changes in food availability and composition due to variable precipitation (Boag and Grant, 1984). For one finch species, wet years result in smaller billed individuals and drought years select for large ones, which leads to frequent shifts in the distribution of bill sizes.

Change in the incidence of extreme high or low temperatures through time can lead to highly skewed population sex ratios in the case of reptiles because sex is often determined during a critical phase of embryonic development (reviewed by Bull, 1980). However, sex ratios may no longer be self-adjusting, as evidenced by the current trends in many wild turtles toward smaller population sizes, fewer and more isolated protected nesting habitats that lead to less-successful dispersal, as well as limited choice of sites for nesting within a habitat. Thus, impacts of shifting climatic distribution in the past cannot be simply extrapolated to the future.

Weather events may provide a cue that affects the timing of breeding. For example, the beginning of the rainy season may signal the onset of a window of time for breeding. Climate variability can influence which group of individuals within a species breeds. In especially wet years when food resources are high, subordinate Galapagos mockingbird females breed opportunistically. In the case of African elephants, dominant males breed in the wet season and subordinate males in the dry season of a given year. A change in the intensity or duration of rainy versus dry seasons may change relative breeding rates and genetic structures within populations (Poole, 1989; Rubenstein, 1992).

Extreme weather can have major impacts on wild populations. Drought has caused crashes in diverse taxa of insect populations (Hawkins and Holyoak, 1998) and booms in populations of other insects (Mattson and Haack, 1987). Heat and cold stresses also can lead to population crashes, including aquatic systems (Huntsman, 1946; Bailey, 1955). Changes at the community level due to extreme events may also have large impacts. The 1982/83 El Niño event caused widespread loss (bleaching) of coral reef communities in the eastern and central Pacific (Coffroth *et al.*, 1990), and hurricanes and typhoons have changed the composition of local communities with regard to the identity and abundance of species (Willig *et al.*, 1998; Willig and McGinley, 1999). Large weather events including hurricanes and typhoons, tornadoes, wildfires, floods, droughts, landslides, and even tree-falls can trigger ecosystem-level disturbances, affecting the organization (species composition and diversity) and functional attributes of systems (Walker, 1999; Walker and Willig, 1999). The initial degree of response of a system and the extent to which it can return to its original conditions after such a disturbance depends on the frequency, intensity, duration, and extent of the disturbance as well as the evolutionary history and extent of exotic invaders (Willig and Walker, 1999; Myers, 1996; Zimmerman *et al.*, 1996; Pickett and White, 1985).

In light of the reality of today's modern human-dominated landscape, in which natural ecosystems are increasingly confined to smaller and more isolated fragments and population sizes of wild nonweedy species have generally declined (Groombridge, 1992), natural systems have limited options by which to contend with the predicted rapid changes in climatic extremes or in frequency and intensity of disturbances. Genetic variation is often diminished by reduced population sizes, limiting the potential for local adaptation. Increases in distances between natural habitats, decrease successful dispersal, and hinder simple shifts of species' distributions. Increased fragmentation also lowers the probability of colonizing devastated areas after catastrophic disturbances. Colonists must travel farther, and their source populations within impoverished communities are smaller.

Modern systems have lowered resiliency to the types of nonlinear dynamic processes predicted by scenarios of global climate change (Schneider and Root, 1996; Easterling *et al.*, 2000; Meehl *et al.*, 2000). We need a more precise understanding of the relationships between biotic processes and extreme weather events to predict the impacts of future changes in the shape and position of the climatic distribution with more than modest confidence.

Examples of Ecological Responses to Climate Changes

Distribution Shifts

As the climate has changed a wide range of taxonomic groups have shifted their ranges because they are attempting to stay in areas where they are exposed to the same regional ambient temperatures, which generally means moving toward the pole and up in elevation. For example, the ranges of 39 butterfly species in Europe and North America have shifted up to 200 m northward over the last three decades (Parmesan *et al.*, 1999). Twelve bird species in Britain have moved an average of 18.9 km northward (Thomas and Lennon, 1999). Some range shifts involve community-level changes. Walther *et al.* (2002) and others point out that changes in distribution are often asymmetrical with species invading faster from lower elevations (Pounds *et al.*, 1999) or latitudes (King and Harangozo, 1998) than resident species shifting their ranges poleward or upslope, resulting in a transient species richness due to the different rates at which ranges shift.

In the early 1900s Joseph Grinnell systematically surveyed a 3000 m elevation gradient in Yosemite National Park. The same area was resurveyed in the early 2000s. Roughly half of the 28 mammals surveyed moved up in elevation by an average of around 500 m. For example, one of the species shifting up in elevation in response to climatic warming is the American pika (*Ochotona princeps*) (Moritz *et al.*, 2008). In 1900 Grinnell found it up to 2400 m, but in 2004 it was recorded as high as 2900 m. The same type of analyses with similar results has also been done on birds (Tingley *et al.*, 2009).

Abundance Shifts

The abundance or density of a species at a given location can change. For example, in Antarctic terrestrial ecosystems, macroscopic plants (largely mosses) are colonizing previously bare or newly exposed ground and the two higher plants on the continent are rapidly expanding their populations as well as their ranges (Convey, 2001; Smith, 2001; Kennedy, 1995). In tandem with the changes in vegetation, soil invertebrates are also colonizing (Walther *et al.*, 2002).

The Living Planet Index aggregates trends of some 3000 wild populations of species (from published sources), which are the result of multiple impacts associated with human activities. It shows a consistent decline in average species abundance of about 40% between 1970 and 2000; inland water species declined by 50%, whereas marine and terrestrial species both declined by around 30% (CBD, 2005). Similar trends have been observed for abundant and widespread bird species breeding on farmland throughout Europe, and for populations of species threatened by extinction. With regard to the abundance and distribution of selected species, most species with limited population size and distribution are being further reduced whereas some invasive species become more common.

Phenology

The timing of different seasonal activities (phenology) of many species is shifting in concert with the changing climate.

Common changes in the timing of spring activities include the timing of migration in various species such as birds, mammals, fish, and insect species (e.g., MacMynowski and Root 2007; Ogdan *et al.*, 2008). Meta-analyses have been performed to look for consistent patterns around the globe over a large number of species. For all northern hemisphere species reported in the literature with more than a 10 year record showing phenological changes in the spring, the average number of days changed in the spring observed over the last 30 years of the twentieth century was ~ 15.5 or ~ 5 days per decade earlier timing for those species showing a phenological change in the spring (Root *et al.*, 2003).

Over evolutionary time species have formed predator–prey relationships that are being disrupted because the predator and prey do not necessarily shift at the same time. For example, the common cuckoo (*Cuculus canorus*) is a migrant and lays its eggs in the nests of other birds that migrate in Europe to its breeding grounds from both short and long distances. With climate change the short-distance migrants are arriving significantly earlier now than in the past and they are nesting before the cuckoo has arrived. Consequently, the short-distant migrants seem to have experienced a way by which to reduce brood parasitism (Saino *et al.*, 2009).

Changes in Physical Structure, Genetics, Metabolism, and Behavior

Physical characteristics that are sensitive to climate include body size, hairiness, length of limbs, and skin or hair color. The average body trait for any given population can be genetically based; however, variation in the body trait of an individual animal can also be caused by variation in the environment experienced by the animal as it develops. Thus, the development of physical traits may involve genetic evolution or merely an immediate, plastic response to a changing environment. Many such traits appear to be affected by past climate changes (Parmesan and Galbraith, 2004).

Hadly (1997), Sullivan and Best (1997), Badgley (1998), and Smith and Betancourt (1998) have documented body size changes of small mammals, lizards, and zooplankton during historical (natural) climate shifts. In a phenomenon first associated with latitudinal trends in temperature now known as “Bergman’s rule,” bodies tend to become smaller with general warming and larger with cooling (Bergmann, 1847) with relatively few exceptions. For example, temporal fluctuations of body size in wood rats are so precise that Smith and Betancourt (1998) labeled them “paleothermometers” because changes in their body sizes are so closely aligned with changes in temperature (Parmesan and Galbraith, 2004). A study by Wolf *et al.* (2009) on two rodents that were captured in southern New Mexico from 1991 to 1998 found strong correlation with a time-appropriate climate variable and hind leg, ear, and body length.

Extinction

As a group the background extinction rate for mammals was estimated using the fossil record, and it is less than one species

each millennium (May 2010). Both mammals and birds have been well studied throughout the past century and their extinction rate over that time period has been around one extinction per year. This rate is up roughly 1000 times the background rate for mammals (May 2010). Attempts have been made to try to understand how many and which species may face extinction in the future.

Range expansions of species at high elevations and latitudes in response to climate-change-generated impacts have been widely documented, but Wilson *et al.* (2005) observe that there has been surprisingly little evidence for contractions at warm margins (Parmesan *et al.*, 1999; Thomas and Lennon, 1999; Hill *et al.*, 2002), even though the first expected symptoms of a climate-induced biodiversity crisis are range contractions and extinctions at lower elevational and latitudinal limits to species distributions. Wilson *et al.* (2005) show that lower elevational limits for 16 butterfly species in the Sierra de Guadarrama (central Spain), a mountain range that represents the lower latitudinal or elevational boundary for many species of butterfly (Gómez de Aizprua, 1987; Kudrna, 2002; García-Barros *et al.*, 2004) have risen on average by 212 m ($\pm$ SE 60) in 30 years. This rise, which accompanies a 1.3 °C rise (equivalent to about 225 m) in mean annual temperature, signifies, on average, a 33% reduction in habitable area. They point out that these declines might be underestimated if there is a time lag in extinctions from sites that are outside the long-term climatic tolerances of the species (Hill *et al.*, 2002). In addition, they project regional habitat losses of 50–80% for the twenty-first century, given maintenance of the species climatic associations and continued regional warming – losses that will, in all probability, be exacerbated by habitat loss resulting from land-use changes. The magnitude of these declines in available habitat may possibly be typical for species that are restricted to high elevations at their warm range margins (Stefanescu *et al.*, 2004), or for endemic taxa that are entirely restricted to mountainous regions (Pounds *et al.*, 1999; Williams *et al.*, 2003). Because suitable high elevations for these species exist in spatial isolation, they are unable to colonize new areas as the climate warms (Grabherr *et al.*, 1994; Pounds *et al.*, 1999; Midgley *et al.*, 2002; Klanderud and Birks, 2003; Konvicka *et al.*, 2003; Williams *et al.*, 2003). Unless climate change and habitat loss can be stopped, widespread extinctions may follow.

Another recent study (Pounds *et al.*, 2006) that implicates climate change as a factor in species extinctions proposes that there is a link between recent climate changes and the spread of a pathogenic chytrid fungus, *Batrachochytrium dendrobatidis*, which appears to have caused a mass extinction of frog and toad species in the mountains of Costa Rica. Seventeen years ago, the Monteverde harlequin frog (*Atelopus* sp.) and the golden toad (*Bufo periglenes*) vanished. According to Pounds *et al.*, this pathogenic chytrid fungus is implicated in the disappearance of an estimated 67% of the 110 or so species of *Atelopus*, which are endemic to the American tropics. After analyzing the timing of species losses in relation to changes in sea-surface temperature and air temperature, Pounds *et al.*, posits with very high confidence that large-scale warming is a key factor in the disappearances. They observed two patterns with regard to a link between climate-induced temperature rise and the chytrid fungus: Firstly, just as the lowlands are often

too warm for the chytrids during the day, the highlands are often too cool for them at night. Secondly, most *Atelopus* extinctions have occurred at elevations where the minimum temperature is shifting toward the growth optimum for these pathogens. Thus, Pounds *et al.* propose the chytrid-thermal-optimum hypothesis, in which daytime cooling (local or microscale) and nighttime warming accelerate disease development, observing that the impacts at night may explain the association with warm years and thereby resolve the climate–chytrid paradox. These findings have garnered mixed reviews from experts on amphibian disease and ecology with some saying that they provide important evidence of another impact that climate change is having on wildlife, whereas others say that there are uncertainties that have not been sufficiently addressed. In this, however, as with all complex problems, in the early phases of learning one looks for multiple lines of argument and when they converge with a basic theory, it increases confidence in a connection.

Meta-Analyses

Meta-analyses provide methods for combining results from various studies, whether statistically significant or not. Results from meta-analyses determine whether there is a consistent “signal” or “fingerprint” among the studies. The balance of evidence from two such meta-analyses done on species from many different taxa examined at disparate locations around the globe (Root and Schneider, 2002; Walther *et al.*, 2002; Parmesan and Yohe, 2003; Root *et al.*, 2003) suggests that a significant impact from recent climatic warming is discernible in the form of long-term, large-scale alteration of animal and plant populations. Though these studies had some significant methodological differences, their basic conclusions were very similar.

Root *et al.* (2003) gathered information on species and global warming from 143 studies, each of which spanned at least 10 years, showed a trait of at least one species that exhibited change over time, and that found either a temporal change in temperature at the study site or a strong association between the species trait and site-specific temperature. To document a strong role for climate change in explaining many of the observed changes in animal and plant populations, Root *et al.* looked for repeated examples occurring over long temporal and broad spatial scales that showed unidirectional changes predicted by the current understanding of the physiological tolerances of species to temperature. The predicted result, or fingerprint, of an underlying consistent shift in a large-scale pattern shown by many species around the globe, coupled with an understanding of the possible causal mechanisms, provides confidence in attributing observed species changes to climatic change.

The Root *et al.* study shows that recent temperature change has already had a marked influence on many species. Their meta-analyses revealed a consistent temperature-related shift in species ranging from mollusks to mammals and grasses to trees with more than 80% of the species showing changes shifting in the direction that would be expected based on species’ known physiological constraints.

For example, their analyses showed an average shift in spring phenology (timing) of events, such as breeding or blooming, for temperate-zone species of 5.1 ± 0.1 days earlier in a decade and strongly suggest that species at higher altitudes are reacting more strongly to more intense changes in temperature.

The conclusion that significant impact from recent climatic warming is discernible in the form of long-term, large-scale alteration of animal and plant populations supported by the meta-analyses discussed above was extended by the IPCC (Intergovernmental Panel on Climate Change (IPCC), 2001b, Chapter 4) to include “environmental systems” – sea- and lake-ice cover and mountain glaciers. Clearly, if such climatic and ecological signals are now being detected above the background of climatic and ecological noise for a twentieth century warming of only 0.6°C , it is likely that the expected impacts on ecosystems of temperature increases up to an order of magnitude larger by 2100 will be dramatic.

Joint Attribution

The meta-analyses discussed above have established that many plant and animal species are responding to regional climatic changes, but can the extent to which such regional warming is natural variation as opposed to attributable to human activities be teased apart? If there is a discernible impact of human activities on climate (Intergovernmental Panel on Climate Change (IPCC), 1996a, b, c, 2001a, b, c, 2007a, b, c) and a discernible impact of climate on plants and animals (e.g., Intergovernmental Panel on Climate Change (IPCC), 2007b), can it be asserted that there is a discernible impact of human-induced climate change on plants and animals, the so-called joint attribution? Root *et al.* (2005) correlated Northern Hemispheric phenological responses of plants and animals reported to be changing over the past 50 years to spring temperature data produced by the HadCM3 climate model. This model was driven by three sets of observed potential causes: (1) only natural forcings (e.g., solar activity and volcanic dust veils), (2) only anthropogenic forcings (e.g., CO_2 and aerosol increases), and (3) combined forcings (i.e., natural and anthropogenic forcings together). Given the many uncertainties and missing factors, it is not expected that most of the variance of observed phenological changes in the past 50 years can be attributed to anthropogenic forcings. Thus, the key question is as follows: Did the correlations between observed plant and animal phenological records improve when anthropogenic forcing was driving the models relative to the correlations when only natural forcings produced the climate-model records? The Root *et al.* (2005) results show a clear signal that, despite known uncertainties and missing factors, springtime temperatures driven by anthropogenic forcing are much more highly correlated with observed phenological changes in plants and animals than are temperatures driven by natural forcing. Human activities are highly likely to be contributing to the changes in regional surface temperatures, and these human-influenced temperature patterns are significantly associated with discernible changes in plant and animal phenological traits.

Climate Modeling: Validation and Forecasts

Constructing Climate Models

The evidence outlined above paints a compelling picture of widespread human-induced climate change impacts on plant and animal species. As mentioned above, these changes are expected to continue and probably accelerate during the twenty-first century. Projections of future ecological changes, informed by projections of future climate changes, are essential to meet the challenge posed by the multiple stressors on biodiversity outlined above.

To predict the ecologically significant ways in which the climate might change, one must estimate a plausible set of assumptions about what people do that modifies how energy is exchanged among the atmosphere, land surface, and space, because such energy flows are the driving forces behind climate. Such driving forces include projections of population, consumption, land use, and technology. The next step is to estimate the response of the various components of the earth system to such societal forcings. The earth system consists of the following interacting subcomponents: atmosphere, oceans, cryosphere (snow, seasonal ice, and glaciers), and land-surface (biota and soils) systems.

Research in the field and in laboratories provides an understanding about various processes affecting the sub-components of the earth system. This understanding can be put into mathematical expressions that, when combined, form a model of the behavior of particular components of the earth system. In practice, models of the atmosphere are connected to models of the oceans, ice, biota, and land surfaces to simulate the consequences of a scenario of societal forcing on climate and ecosystems. Controversy arises because both the societal forcing that will actually occur and the scientific knowledge of each subsystem are incomplete. Because models cannot be perfect replicas of the actual natural system, scientists must expend considerable efforts to test their models against the expanding base of field and laboratory data. This not only allows them to assess the credibility of current simulations but it also reveals improvements for the next generation of models.

Scientists who estimate the future climatic changes that are relevant to ecosystems have focused on general circulation models (GCMs) that attempt to represent mathematically the complex physical and chemical interactions among the atmosphere, oceans, ice, biota, and land. As these models have evolved, increasingly more information has become available, and more comprehensive simulations have been performed. Nevertheless, the complexities of the real climate system still vastly exceed the GCMs and the capabilities of even the most advanced computers (Intergovernmental Panel on Climate Change (IPCC), 1996a, 2001a, 2007a).

Verifying Climate Forecasts

The most perplexing question about climate models is whether they can be trusted as a reliable basis for altering social policies, such as those governing CO₂ emissions or the shape and location of wildlife reserves (other than those based on no-regrets strategies). Even though these models are fraught

with uncertainties, several methods are available for verification tests. Although no method is sufficient by itself, several methods together can provide significant, albeit circumstantial, evidence of a forecast's credibility.

The first validation testing method involves checking the model's ability to simulate the current climate. The seasonal cycle is a good test because temperature changes in a seasonal cycle are larger on a hemispheric average than the change from an ice age to an interglacial period (i.e., 15 °C seasonal range in the Northern Hemisphere vs 5–7 °C glacial–interglacial cycle). GCMs map the seasonal cycle well. This supports the scientific consensus about the plausibility of global warming of several degrees in the twenty-first century. The seasonal test, however, does not indicate how well a model simulates slow processes such as changes in deep ocean circulation, ice cover, forests, or soil carbon storage, which may have important effects on the decade- to century-long timescales over which atmospheric CO₂ is expected to at least double.

A second verification technique involves isolating individual physical components of the model and testing them against actual data. A reasonable model should reproduce the flow of thermal energy among the atmosphere, the surface, and space with no more than about a 10% error. Together, these energy flows make up the well-established natural greenhouse effect on Earth and constitute a formidable and necessary test for all models. A model's performance in simulating these energy flows is an example of the physical validation of model components.

A third validation method involves the model's ability to reproduce the diverse climates of the past. This method is aided by recording instrumental observations made during the past few centuries and paleorecords that serve as a proxy for climatic conditions of the ancient Earth, or even include testing the models' ability to simulate climates of other planets (Kasting *et al.*, 1988). Paleoclimatic simulations of the Mesozoic (Age of the Dinosaurs), glacial–interglacial cycles, or other extreme past climates help scientists understand the coevolution of the Earth's climate and living things (Schneider and Londer, 1984). As verification tests of climate models, they are also crucial to predicting future climates and changes in biological systems.

The joint attribution study mentioned earlier (Root *et al.*, 2005) also served as a verification exercise, since that work tested the correlation of the model-generated temperature records versus phenological patterns of plants and animals locally, regionally, and hemispherically. Root *et al.* (2005) found that, even at the local level, the HadCM3 computer model predicted much more of the variance of the observed species records for anthropogenic forcing than for natural forcing, and even more of the variance for a combination of natural and anthropogenic forcing. This is a powerful proxy technique for model verification at even a local scale – the level for which climate modelers are most cautious to claim skill levels.

Downscaling Climate Predictions to Regional Effects

Even the highest resolution, three-dimensional GCMs do not have a grid with nodes less than 100 km apart; individual clouds and most ecological research (to say nothing of cloud

droplets) occur on scales far smaller. Therefore, GCMs will not be able to resolve the local or regional details of weather affecting most local biological communities or the importance of regional effects of hills, coastlines, lakes, vegetation boundaries, and heterogeneous soil (Root and Schneider, 1993). Nonetheless, it is important to have climatic projections and ecological-response analyses on the same physical scales.

What is most needed to evaluate potential biological effects of temperature change is a regional projection of climatic changes that can be applied to ecosystems at a regional or local scale. Analyses of large, prehistoric climatic changes (Barron and Hecht, 1985; Budyko *et al.*, 1987; Schneider, 1987; Cooperative Holocene Mapping Project, 1988) and historical weather analogs (Pittock and Salinger, 1982; Jager and Kellogg, 1983; Lough *et al.*, 1983; Shabalova and Können, 1995) provide some insights into such changes. Historical weather analogs, however, since they are empirically and statistically based, rely on climatic cause-and-effect processes that probably differ from those that will be driven by future greenhouse gas radiative effects (Schneider, 1984; Mearns *et al.*, 1990; Crowley, 1993). Consequently, ecologists turn to climatic models to produce forecasts of regional climatic changes for the decades ahead. How credible are such forecasts?

Statistical Downscaling Techniques

Techniques exist that can translate the output of climate models so that it is closer to that of most ecological scales. One method that uses actual climatic data at both large and small scales can help provide maps that may allow small-scale analysis of large-scale climate change scenarios. For example, the Sierra Nevada of California or the Cascades in the north-western US are north-south mountain chains east-west dimensions smaller than the grid size of a typical GCM. In the actual climate system, onshore winds on the Pacific coast would produce cool upslope and rainy conditions on the western slope and a high probability of warmer and drier conditions associated with that flow pattern on the downslope or eastern slope.

Researchers have developed statistical downscaling techniques that link large-scale climatic patterns to small-scale climatic conditions. For example, the analysis of Hayhoe *et al.* (2004) relied on a deterministic method in which grid-cell values of temperatures and precipitation from two GCMs were used to produce weather-station-level data for California, by rescaling the data using simple monthly regression relations to ensure that the overall probability distributions of the simulated daily values closely approximated the observed probability distributions at selected long-term weather stations (Dettinger *et al.*, 2004). The same regression relations were then applied to future simulations, such that rescaled values share the weather statistics observed at the selected stations. These methods allow the reproduction of the dominant mode of variation for this area (warm and dry on one side of the mountains and cold and wet on the other side). Although such a statistical downscaling technique seems appropriate for translating low-resolution, grid-scale climate-model forecasts to local applications, a strong caveat must be offered. That is, the processes in the climate system that give rise to internal

variability or natural fluctuations are not necessarily the same processes that would give rise to local deviations from large-scale patterns if the climate change were driven by external forces rather than an internal variation of the system. The conditions produced using such a method reflect the most probable regional situation for today's naturally fluctuating climate. However, if 50 years from now, as the result of on-going emissions producing an enhanced downward infrared radiative heating, then both eastern and western slopes of the Sierra Nevada would probably experience warming, and an entirely different climatic change pattern linking large- and small-scale processes would probably occur. This pattern would be different than that obtained from statistical downscaling techniques using the naturally varying weather conditions existing today rather than the anthropogenically forced conditions of the twenty-first century.

Therefore, techniques to downscale climate forecasts that use current distributions of environmental variables at local scales and correlate them with current large-scale regional patterns may not necessarily provide a good guideline about how large-scale patterns would be distributed regionally. This is especially true if there are changes in prevailing winds, seasonality or cloud cover. The reason is that the causes of the future change may be physically or biologically different from the causes of the historical fluctuations that led to the empirical maps in the first place. This caveat warns scientists to use caution before adopting such empirical techniques for global change applications.

There are practical limits to downscaling, especially using global techniques. Downscaling to a weather station, assuming that the weather-station data are accurate (a dubious assumption in many parts of the world and the above caveats are heeded), provides useful information at the level of the point. Gridded weather data are often used when weather-station data are not available. These grids are typically $0.5^\circ \times 0.5^\circ$ of latitude and longitude in size, but the uncertainties in gridding areas with sparse data and with large elevational changes must be recognized. The standard gridded data set used in many studies is the Climate Research Unit (CRU) TS data (University of East Anglia Climate Research Unit). In some areas with large numbers of weather stations (e.g., US, Europe, Australia) smaller grids (approximately 10 km^2) have been developed (e.g., VEMAP, OzClim). Although it is theoretically possible to downscale to such small scales and even smaller ones (1 km^2 based on digital elevation model data), caution must be taken when using any of these gridded data. At a large scale (50 km^2) the differences in slopes of mountains are rarely picked up. At 1 km^2 , elevation is important, but slopes, aspect and, especially wind direction and water transport are essential when calculating lapse rate to estimate temperature and vital for precipitation estimates.

Regional-Scale Models with GCM Inputs (Dynamical Downscaling)

Other techniques can still translate large-scale patterns to smaller scales, but these techniques are based on known processes rather than empirical maps for today's conditions. One such technique is to drive a high-resolution, process-based model for a limited region with the large-scale patterns produced by a GCM. In essence, this approach uses a

mesoscale model (i.e., 10–50-km² grid cells) based on physical laws to solve the problem of translating GCM grid-scale averages into a finer scale mesh much closer to the dimensions of most ecological applications. Of course, even this mesoscale grid will still be too coarse to assess many impacts, necessitating further downscaling techniques. Neither are the problems of GCMs entirely eliminated by mesoscale grids because they are still bigger than individual clouds or trees. However, such methods do bring climate-model scales and ecological-response scales much closer.

Ecological Modeling Based on Future Climate Projections

Bringing climatic forecasts to ecological applications at local and regional scales is one way to bridge the scale gap across ecological and climatological studies. Ecologists, however, have also analyzed data and constructed models that apply over large scales, including the size of climatic model grids. A long tradition in ecology has associated the occurrence of vegetation types or the range limits of different species with physical factors such as temperature, soil moisture, land–sea boundaries, or elevation. Biogeography is the field that deals with such associations, and its results have been applied to estimate the large-scale ecological response to climate change.

Methods

Top-Down Approaches

The biogeographic approach is an example of a top-down technique (e.g., Holdridge life zone classification), in which data on abundances or range limits of vegetation types or biomes are overlain on data of large-scale environmental factors such as temperature or precipitation. When associations among large-scale biological and climatic patterns are revealed (Root, 1988b), biogeographic rules expressing these correlations graphically or mathematically can be used to forecast changes in species driven by given climate changes.

Top-down approaches suffer because of the possibility that the discovered associations at large scales are statistical artifacts that do not, even implicitly, reflect the causal mechanisms needed for reliable forecasting. As Jarvis (1993, p. 121) stated, “A major disadvantage of a top-down model is that predictions cannot be made safely outside the range of the variables encountered in the derivation of the lumped parameter function.”

Bottom-Up Approaches

Another traditional analysis and forecasting technique is often referred to as bottom-up. Small-scale ecological studies have been undertaken at the scale of a plant or even a single leaf (Idso and Kimball, 1993) to understand how, for example, increased atmospheric CO₂ concentrations might directly enhance photosynthesis, net primary production, or water-use efficiency. Most such studies indicate increases in all these factors – increases that some researchers have extrapolated to ecosystems (Idso and Brazel, 1984; Ellsaesser, 1990).

However, at the scale of a forest, the forest regulates the relative humidity within the canopy, which significantly influences the evapotranspiration rate. In other words, if an increase in water-use efficiency decreased the transpiration from each tree, the aggregate forest effect would be to lower relative humidity. This, in turn, would increase transpiration, thereby offsetting some of the direct CO₂/water-use efficiency improvements observed experimentally at the scale of a single leaf or plant. Regardless of the extent to which this forest-scale feedback effect will offset inferences made from bottom-up studies of isolated plants, the following general conclusion emerges: the bottom-up methods may be appropriate for some processes at some scales in environmental science, but they cannot be considered credible without some sort of validation testing at the scale of the system under study. For bottom-up models, the primary problem is that some of the most conspicuous processes observable at the smaller scales may not be the dominant processes that generate large-scale patterns. In this connection, multifactorial studies were conducted at Jasper Ridge in California, in which a grassland ecosystem was subjected to enhanced CO₂, enhanced CO₂ and temperature, enhanced CO₂ and temperature and moisture stress, and enhanced CO₂ and temperature and moisture stress and nutrient stress. What was observed was that this multifactorial analysis greatly reduced the benefits of CO₂ enhancements observed in single species, one-factor experiments. Although it is premature to over generalize, the implication is clear – single species or single-factor experiments are not likely to be very predictive for actual responses of ecosystems to climate and CO₂ changes in the decades ahead.

Combined Top-Down and Bottom-Up Approaches

To help resolve the deficiencies of the sole use of top-down biome forest models mentioned previously, more process-based, bottom-up approaches such as forest gap models have been developed (Botkin *et al.*, 1972; Pastor and Post, 1988; Smith *et al.*, 1992). These models include individual species and can calculate vegetation dynamics driven by time-evolving climatic change scenarios. However, the actual growth rate calculated in the model for each species has usually been determined by multiplying the ideal growth rate curve by a series of growth-modifying functions that attempt to account for the limiting effects of nutrient availability, temperature stress, and so forth. These growth-modifying functions for temperature are usually determined empirically at a large scale by fitting an upside-down U-shaped curve, with maximum temperature midway between the average temperature of the species' northern-range limit and the average temperature of its southern-range limit. Growing degree-days (related to temperature but not temperature *per se*) are used in this scenario.

In essence, this technique combines large-scale, top-down empirical pattern correlations into an otherwise mechanistic bottom-up modeling approach. Although this combined technique refines both approaches, it has been criticized because such large-scale, top-down inclusions are not based on the physiology of individual species and lead to confusion about the fundamental and realized niches (Pacala and Hurtt, 1993). (The fundamental niche is the ecological space in which a given species could theoretically survive – e.g., if its

competitors were absent – and the realized niche is where it actually exists.) The question is then, what limits the realized niche, particularly at the southern boundary? Furthermore, more refined models should include factors such as seed dispersal so that plant recruitment is related to the preexisting population and is not simply the result of a random number generator in the computer code.

Studies of More Refined Approaches

As noted previously, problems with the singular use of either top-down or bottom-up methods have led to well-known criticisms. A search of the literature (Wright *et al.*, 1993; Root, 1994; Harte and Shaw, 1995) provides examples of a refined approach to analyzing across large and small scales, which Root and Schneider (1995, 2003) labeled strategic cyclical scaling. This method builds on the combined techniques in which top-down and bottom-up approaches are applied cyclically in a strategic design that addresses a practical problem: in our context, the ecological consequences of global climatic change. Large-scale associations are used to focus small-scale investigations; this helps ensure that tested causal mechanisms are generating the large-scale relations. Such mechanisms become the laws that allow more credible forecasts of the consequences of global change disturbances. Levin (1993, p. 14) observed: “Although it is well understood that correlations are no substitute for mechanistic understanding of relationships, correlations can play an invaluable role in suggesting candidate mechanisms for (small-scale) investigation.”

Strategic cyclical scaling, however, is intended not only as a two-step process but also as a continuous cycling process between large- and small-scale studies, with each successive investigation building on previous insights from all scales. This approach is designed to enhance the credibility of the overall assessment process (Vitousek, 1993; Harte and Shaw, 1995), which is why strategic is the first word in strategic cyclical scaling.

If the rate at which humans are injecting GHGs into the atmosphere is not greatly decreased, the Earth’s climate will most likely warm by several degrees Celsius by 2050 (Intergovernmental Panel on Climate Change (IPCC), 2007a). With this in mind, Root (1988a, b) examined the biogeographic patterns of all wintering North American birds. She chose this group of species because birds are important parts of ecosystems and because of the availability of the necessary data. The National Audubon Society and the US Geological Survey have volunteer forces amassed to aid in the collection of Christmas Bird Count data and Breeding Bird Survey data, respectively. Using Christmas Bird Count data, Root determined that for a large proportion of species, average distribution and abundance patterns are associated with various environmental factors (e.g., the northern-range limits of some species are apparently limited by average minimum January temperature; Root, 1988a, b, 1989; Repasky, 1991).

The following is the scaling question: What mechanisms (such as competition or thermal stress) at small scales may have given rise to the large-scale associations? Root first tested the hypothesis that local physiological constraints may be causing most of the particular large-scale, temperature-range boundary associations. She used published small-scale studies

on the wintering physiology of key species to determine that about half of the songbird species wintering in North America extend their ranges no farther north than the regions where, to avoid hypothermia during winter nights, they need not increase their metabolic rates more than ~2.5 times their basal metabolic rate (Root, 1988b). Root embarked on a larger, regional study to determine whether the longer nights – hence, fewer hours of daylight available for foraging – or the colder temperatures in the more northerly locations are relatively more important. Preliminary results indicate that changing temperatures are more likely than day length to explain this effect (Root, unpublished data): thus, global temperature changes are predicted by this set of analyses to cause a rapid range and abundance shift, at least by selected bird species. Indeed, Root initially found significant year-to-year shifts in ranges and abundances; these shifts are apparently associated with year-to-year changes in winter temperatures.

Then, much more recently, the meta-analyses of Parmesan and Yohe (2003) and Root *et al.* (2003), as well as the joint attribution study of Root *et al.* (2005) – and the more recent phenological meta-analysis of Menzel *et al.* (2006) – clearly demonstrate a consistent shift of species in response to the warming of the late twentieth century, where the vast majority of species observed to be changing in the direction expected from physiological ecology: poleward, up mountains, and advances in spring phenology.

Progress toward a way of accounting for the impact of biological interactions on species distribution was recently made by incorporating projections of marine primary productivity into a dynamic bioclimatic envelope model (Cheung *et al.*, 2009). Inclusion of indirect impacts of climate change on a species’ distribution by factoring in the direct impacts on prey species is likely to greatly improve their accuracy due to the more responsive nature of lower trophic levels to environmental variation (Ottersen *et al.*, 2010). A new approach using combined behavioral and biophysical modeling has also drawn attention to the high risks to terrestrial ectotherms such as insects, frogs, lizards, and turtles in tropical and desert regions such as Australia (Kearney *et al.*, 2009).

Studies

Predicting Vegetation Responses to Climate Change

The classical Holdridge (1967) life zone classification assigns biomes (e.g., tundra, grassland, desert, or tropical moist forest) according to two measurable variables – temperature and precipitation. Other more complicated large-scale formulas have been developed to predict vegetation patterns from a combination of large-scale predictors (e.g., temperature, soil moisture, or solar radiation); vegetation modeled includes individual species (Davis and Zabinski, 1992), limited groups of vegetation types (Box, 1981), or biomes (Prentice *et al.*, 1992; Melillo *et al.*, 1993; Neilson, 1993). These kinds of models predict vegetation patterns that represent the gross features of actual vegetation patterns, which are incentives used to predict vegetation change with changing climate, but they have some serious drawbacks as well. That is, they are typically static, not time-evolving dynamic simulations, and thus cannot capture the transient sequence of changes that

would take place in reality. In addition, such static biome models occasionally make “commission errors,” that is, they typically predict vegetation types to occur in certain zones where climate would indeed permit such vegetation, but other factors such as soils, topography, or disturbances such as fire actually preclude it. However, newer dynamic general vegetation models (DGVMs) have started to include disturbance regimes. These DGVMs, which work at the level of the plant functional type (PFT, similar to biomes), have been used to look at potential changes in net primary productivity as well as changes in plant groups over time. One of the problems with using DGVMs in a predictive sense is that they are typically “on” or “off” – that is, they show what the current PFT might be and what the future PFT might be but they lack a transition state. This can be misleading for policy makers as it misses the critical information both as to the longevity of some of these PFTs in the absence of disturbance (i.e., reproduction stops but individuals persist for the lifetime of the organisms, potentially several hundred years) as well as the slow rate of dispersal for many plant species. Thus a transition state, matching neither the current nor future PFT is likely. This can be overcome, to some extent by looking at individual species but the large number of species involved, until recently, has made it difficult to look at changes at this scale. The access of large clusters of computers and global datasets, however, has meant that large-number-of-species models can now be run. For example, one particular effort called the Wallace Initiative has modeled almost 50,000 terrestrial plant and animal species. Furthermore, local patterns may influence vegetation dynamics at scales not captured in some simulations, and seed germination and dispersal mechanisms are also either not explicitly simulated or simulated only crudely with such models. It is remarkable that they are still able to produce generalized maps of vegetation types that do indeed resemble current or even paleoclimatic patterns in a broad sense, but their details do not provide confident projections for future vegetation states. Fortunately, progress is being made to include some of the deficiencies mentioned previously, and the so-called dynamical global vegetation models are being developed to treat the transient nature of vegetation change that would probably accompany climatic change.

Using the integrated assessment model IMAGE to link different ecological impacts to different levels of climate change, Leemans and Eickhout (2004) have predicted the impacts of climate change on terrestrial species, ecosystems, and landscapes over a range of increasing global mean temperatures and the corresponding temperature and precipitation patterns for the twenty-first century. Although there are large regional differences, their analysis shows that even small increases in global mean temperatures will considerably impact many species, ecosystems, and landscapes – especially such temperature-limited ecosystems as tundra. At an increase of between 1 °C and 2 °C in global mean temperatures, most species, ecosystems, and landscapes will be affected and adaptive capacity will become limited.

At a rate of warming of 0.1 °C per decade (i.e., 1 °C global mean temperature increase by 2100), Leemans and Eickhout's analysis predicts that 50% of all ecosystems will be able to adapt within a century, but only 36% of all affected forests. At a rate of warming of 0.3 °C per decade (i.e., 3 °C global mean

temperature increase in 2100), only 30% of all affected ecosystems will be able to adapt and only 17% of all affected forests. Leemans and Eickhout observe that with the current rate of climate change (which is >0.2 °C per decade), a decline in biodiversity will accelerate and simultaneously many ecosystem services will become less abundant.

Predicting Animal Responses to Climate Change

Scientists of the US Geological Survey, in cooperation with Canadian scientists, conduct the annual North American Breeding Bird Survey, which provides distribution and abundance information for birds throughout the US and Canada. From these data, collected by volunteers under strict guidance from the US Geological Survey, shifts in bird ranges and abundances can be examined.

Because these censuses were begun in the 1960s, these data can provide a wealth of baseline information. Price (1995) used these data to examine the birds that breed in the Great Plains. Using the present-day ranges and abundances for each of the species (Figure 2(a)), Price derived large-scale, empirical-statistical models based on various climate variables (e.g., maximum temperature in the hottest month and total precipitation in the wettest month) that provided estimates of the current bird ranges and abundances (Figure 2(b)). Then, using a GCM to forecast how doubling of CO₂ might affect the climate variables in the models, he applied the statistical models to predict the possible shape and location of the birds' ranges and abundances (Figure 2(c)).

Significant changes were found for nearly all birds examined. The ranges of most species moved north, up mountain slopes, or both. The empirical models assume that these species are capable of moving into these more northerly areas, provided habitat is available and no major barriers exist. Such shifting of ranges and abundances could cause local extinctions in the more southern portions of the birds' ranges, and, if movement to the north is impossible, extinctions of entire species could occur. We must bear in mind, however, that this empirical-statistical technique, which associates large-scale patterns of bird ranges with large-scale patterns of climate, does not explicitly represent the physical and biological mechanisms that could lead to changes in birds' ranges. Therefore, the detailed maps should be viewed only as illustrative of the potential for very significant shifts with different possible doubled CO₂ climate change scenarios. More refined techniques that also attempt to include actual mechanisms for ecological changes are discussed later. Many think that birds may be able to keep up with rate of climate change because they can fly. However, rates of natal dispersal should not be confused with the expansion capability of populations.

Reptiles and amphibians are different from birds in many ways that are important for our discussion. First, because they are ectotherms – meaning that their body temperatures adjust to the ambient temperature and radiation of the environment – they must avoid environments in which temperatures are too cold or too hot. Second, amphibians must live near water not only because the reproductive part of their life cycle is dependent on water but also because they must keep their skin moist because they ‘breathe’ through their skin as well as their lungs. Third, neither reptiles nor amphibians are able to disperse as easily as birds because they must crawl rather than fly,

Figure 2 (a) Map of current range and abundance of the bobolink as determined from actual observations during the US Geological Survey Breeding Bird Survey and (b) map of current range and abundance of the bobolink as estimated from the empirical-statistical model. The high correspondence in patterns between the maps in (a) and (b) suggests that this model reliably captures many of the features of the actual observed range and abundance of this species as depicted in the map in (a). (c) Map of the forecasted range and abundance of the bobolink for climate change response of a model with doubled CO_2 . This map illustrates the potential for very significant shifts that doubled CO_2 would cause.

and the habitat through which they crawl must not be too dry or otherwise impassable (e.g., high mountains or super-highways). Work by Araujo (2004) looking at patterns of richness of these species in Europe shows that they essentially do not disperse.

As the climate changes, the character of extreme weather events, such as cold snaps and droughts, will also change (Karl *et al.*, 1995), necessitating relatively rapid habitat changes for most animals. There is increasing evidence of experienced and projected effects on animals of changes in climate variability.

For example, population reductions in flying foxes and other species (Welbergen *et al.*, 2008; Thibault and Brown, 2008) and displacement (Kelly and Goulden, 2008) have been detected. Species will need to move into areas that are cooler/wetter (or both), much as they would in a warming climate. This means that barriers, even roads, which often cause high mortality, can be obstacles. For example, the role of extreme events and climate variability is still not adequately taken into account in models of species ranges. Recent work based on three different methods has suggested that species in the

tropics are more in danger of extinction because they already live close to their thermal tolerance. Wright *et al.* (2009) compare distances to cool refuges, finding that 20% of tropical mammal species would have to travel more than 1000 km to a cool refuge under a moderate climate change scenario compared with only 4% of small-ranged extratropical mammal species. Deutsch *et al.* (2009) show how, due to physiological constraints, tropical insect abundance may decline rapidly for quite small climate changes, whereas in temperate regions, insect abundance might be expected to increase with warming. Recent projections for impacts in marine systems show dramatic turnovers of 60% of fish assemblages under climate change, which could disrupt marine ecosystem functioning (Cheung *et al.*, 2009).

Three-Way Linkages and Community Ecology

Anticipated changes in plant ranges will probably have dramatic effects on animals, both on the large biogeographic scale and on the local regional scale. The ranges of many animals are strongly linked to vegetation. For example, red-cockaded woodpeckers are endemic to mature longleaf pine and pine-oak forests (Mengel and Jackson, 1977), and the winter range of Sprague's pipit is coincident with bluestem, a grass (Root, 1988c). Consequently, the ranges of various animals that rely on specific vegetation will change as the ranges of these plants shift, assuming that some other factor is not limiting them. If the climate changes more rapidly than the dispersal rates of the plants, it will very likely result in extensive plant die-offs in the south or downslope before individuals can disperse and become established in the north or upslope. Thus, the ranges of animals relying on these plants could become compressed, and in some instances both the plants and the animals could become extinct. For instance, the red-cockaded woodpecker needs mature, living trees for nesting sites (Jackson, 1974), and if increasing temperature causes most large trees to die before the newly established dispersing trees mature enough, then this woodpecker, federally listed as endangered, could easily become extinct.

Many animal species have ranges that are not directly limited by vegetation but are instead restricted by temperature. This is true for most ectotherms (insects and related arthropods, amphibians, and reptiles) as well as some endotherms (mammals and birds). For example, the Eastern Phoebe, a North American songbird, winters in the US in areas with average minimum temperatures warmer than -4°C (Root, 1988a, b). As the Earth warms, those species directly limited by temperature will be able to expand northward as rapidly as their dispersal mechanisms will allow, again assuming other factors are not limiting them. The animals limited by vegetation will be able to expand their ranges only as rapidly as the vegetation changes. Consequently, the potential for significant disruption among communities is high. For instance, some animals may no longer be able to coexist because an invading species disrupts the balance between competing species or between predator and prey. Therefore, to understand the ecological consequences of global climatic change on animals, the three-way linkages among animals, plants, and climate must be understood. It is critical to realize that this is not simply a one-way process whereby climate influences biota but rather a three-way process because animals and plants

affect each other and are affected by climate. At the same time, altered surface vegetation can affect climate because mid-continental summer precipitation is significantly influenced by water vapor from evapotranspiration (Ye, 1989; Salati and Nobre, 1991). There is increasing evidence of climate-change-induced alterations in ecosystem composition and function (e.g., nutrient cycling, productivity, and community dynamics; Bertin, 2008; Olofsson *et al.*, 2009). In particular shifts have already occurred in several marine food webs (Byrnes *et al.*, 2007; Alheit, 2009) as a result of (observed) changes in sea-surface temperature and (separately) of natural climate variability. This shows how likely future climate change will analogously affect species composition and hence ecosystem functioning and potentially biogeochemical cycles. Recent studies simulate the impacts of combinations of climate changes and their impacts on ecosystems and generally show larger impacts than previously anticipated. For example, an increased die-off of tree species is expected in response to the combination of increased temperatures and increased drought frequency (Adams *et al.*, 2009), and climate-induced shifts in key aquatic species can reduce the resilience of the process that maintains lakes in a clear state (Mooij *et al.*, 2009).

Predicting Extinction

As discussed above, impacts from climate change have already been observed on animal and plant species' distributions, abundances, and phenologies over the last ~ 30 years (Parmesan and Yohe, 2003; Root *et al.*, 2003). A large number of independent studies now project that many species ranges will be reduced so much by climate change that they will be committed to extinction. For example, there are estimates that many small mammals living near isolated mountaintops (which are essentially habitat islands) in the Great Basin would become extinct given typical global change scenarios (MacDonald and Brown, 1992). Studies of small mammals in Yellowstone National Park show that statistically significant changes in both abundances and physical sizes of some species occurred with historical climate variations (which were much smaller than most projected climate changes for the next century), but there appear to have been no simultaneous genetic changes (Hadley *et al.*, 1997). Therefore, it is likely that climate change in the twenty-first century could cause substantial alteration to biotic communities, even in protected habitats such as Yellowstone National Park.

Thomas *et al.* (2004) used projections of 1103 species' distributions for future climate scenarios to assess extinction risks for sample regions that cover some 20% of the Earth's terrestrial surface. These scientists explore three approaches in which the estimated probability of extinction shows a power-law relationship with geographical range size. They predict, on the basis of midrange climate-warming scenarios for 2050, that 15–37% of species in their sample of regions and taxa will be "committed to extinction." When they averaged the three methods and two dispersal scenarios, minimal climate-warming scenarios produced lower projections of species committed to extinction ($\sim 18\%$) than midrange ($\sim 24\%$) and maximum change ($\sim 35\%$) scenarios. However, even minimal climate-warming scenarios, which produced lower percentages of species expected to be committed to extinction, show the importance of reducing GHGs. Despite many

unknowns that exist in projecting extinctions, including a lack of information on the time lag between climate change and species-level extinctions, the effects of including land use in the analyses of extinction risk and the uncertainty about which species will inhabit parts of the world that are projected to have climates for which no current analog exists, Thomas *et al.* report that the consistent overall conclusions across analyses establish that anthropogenic climate warming at least ranks alongside other recognized threats to global biodiversity and is likely to be the greatest threat in many if not most regions. However, they caution that most severe impacts of climate change are likely to result from the interactions of various threats rather than from climate acting in isolation, synergisms that their calculations did not take into account.

Using different methods Malcolm *et al.* (2006) provides an overall estimate of extinctions of endemics in biodiversity hotspots, and generally supports the findings of Thomas *et al.* (2004). Fischlin *et al.* (2007) summarize extinction risks under various levels of global mean temperature rise, estimating that 20–30% of species studied would be at risk of extinction if global temperature rise exceeds 2–3 °C. A meta-analysis of some 80 studies linking quantitative changes in climate change with projected quantified extinction risks for species found increased impacts on ecosystems with increased annual global mean temperature rise (Warren *et al.*, 2011). Substantial increases in extinction risks are commonly projected as the global average temperature reaches and exceeds 2 °C, especially in biodiversity hotspots.

Sekercioglu *et al.* (2008) also discuss the vulnerability of highland species to climate change, in this case, highland bird species. To approximate the effects of elevational distribution on avian extinction risk, they define an elevational area index that is the number of square kilometers of cone surface area a bird species, with its current elevational range, would occupy on an idealized mountain. This is analogous to actual land-surface area available to a bird and makes it possible to compare, for all land bird species, the limitations of elevation on area. Based on this index, which is not sensitive to the model-mountain's shape or size, Sekercioglu *et al.* show that differences in elevational distribution explain 94% of the variation in the proportions of bird species facing a risk of extinction, based on the International Union of Conservation of Nature and Natural Resources (IUCN) definitions of near threatened and threatened. This means that by knowing the elevational distribution of a bird species, one can correctly predict its likelihood of risking extinction 94% of the time, which is not only ecologically interesting, but also has significant conservation implications for birds and other terrestrial taxa. Furthermore, 92% of the variation is explained after various sensitivity analyses regarding the choices of parameters and species. The fact that this relationship is insensitive to large variations in uncertain criteria supports their confidence in the robustness of the results. Equally importantly, by utilizing a modeling approach that combines this index with a wide range of temperature lapse rates, elevational-limitation scenarios, and IPCC surface-warming projections for 2100, Sekercioglu *et al.* estimate that intermediate climate change effects may result in ~600 land bird extinctions and threaten an additional 330 species with extinction. The worst case scenario projects nearly 3200

extinctions – 38% of all land birds. As well as testing the robustness of the relationship between elevational distribution and extinction risk, they also bracketed the uncertainty for climate change scenarios.

Although the climate change extinction-rate estimates are often criticized, it needs to be borne in mind that these are based on MEAN climates. Even the variables taken as 'extreme' are normally not true extremes, but are averages over a month. Mortality in species is often measured in x number of days exceeding a certain threshold (the same as for coral bleaching). Thus, because the return rates of these threshold events will increase as the climate warms, then extinctions, or at least local extirpations, may very well happen sooner than projected by changes in the mean.

As mentioned above, the ability of species to reach new climatically suitable areas will be hampered by habitat loss and fragmentation, and their ability to persist in appropriate climates is likely to be affected by new invasive species. Indeed a recent study by Barnosky *et al.* (2011) indicates that we may be at the beginning of a mass extinction event. Five such extinction events, during which ~75% of species go extinct per event, have occurred on our planet, but this would be the first one caused by only one species.

Recommendations

Improve Regional Analysis, Study Transients, and Include Many Variables

The most reliable projections from climatic models are for global-scale temperature changes. Ecological impact assessments, however, need time-evolving (transient) scenarios of regional to local-scale climate changes: included are changes in precipitation; severe storm intensity, frequency, and duration; drought frequency, intensity, and duration; soil moisture; frost-free days; intense heat waves; ocean currents; upwelling zones; near-ground ozone; forest canopy humidity; and ultraviolet radiation and total solar radiation reaching the surface, where photosynthesis is important. Data gathered at many scales and by coordinated volunteer and professional sources are needed for archives of these regional and local variables, which in turn can be used to develop and test models or other techniques for climatic forecasting.

Adaptability

Our current inability to credibly predict time-evolving regional climatic changes has many implications, one of which concerns the adaptability of agricultural ecosystems. That is, any experience farmers might have with anomalous weather in, for example, the 2020s may not help them adapt to the evolving climate change in the 2030s because a transient climate change could differ dramatically over time. This would inhibit learning by doing, creating a potential lack of adaptability associated with the difficulty of reliably predicting regional climatic consequences (Schneider *et al.*, 2000). Such rapid climate changes would be especially difficult for natural ecosystems to adapt to because habitats do not have the luxury of 'choosing' to plant new seeds or change irrigation systems, soil tillage practices, or other agricultural practices.

There is a growing debate in the natural resources management field over the degree to which natural ecosystems are able to adapt to current and future changes, given that they have been exposed to past climatic changes. Paleoecological studies, and studies on current range and phenological shifts, indicate that the natural response of many species has been, and is, to move or shift to track suitable climatic conditions. Some have argued that the amount of change that some communities have survived in the past might leave them with the ability to survive equivalent changes in the future. This is very difficult to demonstrate. An approach would be to identify, using paleoclimatology, the amount of change ecological communities might have been exposed to in the past and infer that they would be able to survive an equivalent amount of change in the future. Such analyses present many difficulties that include the following: (1) having a paucity of needed large-scale, very long-term appropriately continuous datasets for most species, (2) making risky assumptions on the rate at which species are able to autonomously adapt (behaviorally, physiologically, or evolutionarily) relative to the rate of change not only in the climate but also in other members of the ecological and human-modified landscapes and communities, and (3) overlooking that such changes in the past occurred in much more intact landscapes – lacking barriers of roads, cities, and agricultural fields. Given that the current velocity of climate change is generally thought to exceed already the rate of autonomous adaptation (including movement rates) of most species, then the precautionary principle would dictate that an assumption of autonomous adaptability not be made. The precautionary principle would dictate that efforts to conserve biodiversity in the face of climate change, except perhaps in species with very high birth rates, rely on changing natural resource management practices and for integrating natural resource protection with livelihood protection in the face of a rapidly warming world.

Ecological Applications-Driven Climatic Research

Regional projections of climatic change arising from a variety of greenhouse gas and sulfur oxide emissions scenarios are essential for ecological applications. Such studies must stress the climatic variables most likely to have significant effects on biological resources. For example, extreme variability measures such as high temperature and low relative humidity are important for evaluating the risk of forest fires (Torn and Fried, 1992). Identifying such variables of ecological importance and communicating this information to climate scientists require close interdisciplinary, multi-institutional, and cross-scale research efforts to ensure that combinations of variables relevant to ecological applications receive research priority by climatologists. A focus of climate research toward changing climatic variability (Mearns *et al.*, 1984, 1990; Rind *et al.*, 1989) might be more useful for ecological impact assessments than the current focus among climatic modelers on climatic means.

Interactive, Multiscale, Ecological Studies Needed

Conservation biologists and others face a number of challenges regarding climate change over the next several

decades, both in predicting and documenting its patterns and in dealing with its effects. Most ecological studies project the response of one species at small scales or shifts in biomes at large scales to an equilibrium, CO₂-doubled climate model (e.g., the *Vegetation/Ecosystem Modeling and Analysis Project (VEMAP)*, 1995). What is needed for more realistic and useful ecological impact assessments is a multiscale, multispecies, and multitaxa analysis driven by regionally specific, transient climatic change forecasts. The construction of ecological forecast models first requires large-scale datasets gathered locally by professional (e.g., US Geological Survey landcover datasets) and volunteer (e.g., National Audubon Society Christmas Bird Count) workers. Without such datasets, virtually no credible progress is possible in determining large-scale patterns of associations among ecological and climatic variables. Small-scale studies informed by large-scale patterns are then needed to refine causal mechanisms underlying such large-scale associations, thereby testing the formulas used to make projections of various species or biome responses to hypothesized global changes. For example, Pacala and Hurtt (1993) suggested small- to medium-scale experiments to improve forest gap models. Their criticisms suggest that largely first principles, bottom-up models may still be unrealistic if some top-down parameters (i.e., growth-modifying functions in the instance of gap models) are not appropriately derived from data at the scale at which the models are being applied (Root and Schneider, 1995).

One obvious truism emerges: credible modeling required for forecasting across many scales and for complex interacting systems is a formidable task requiring repeated testing of many approaches. Nevertheless, tractable improvements in refining combined top-down and bottom-up techniques can be made. It will, however, take more than one cycle of interactions to reliably address the cross-scale and multi-component problems of ecological assessment. The strategic cyclical scaling paradigm has two motivations: (1) better explanatory capabilities for multiscale, multicomponent interlinked social-natural systems (e.g., climate-ecosystem interactions or behavior of adaptive agents in economic models responding to the advent or prospect of climatic changes) and (2) more reliable impact assessments and problem-solving capabilities – predictive capacity – as requested by the policy community (Root and Schneider, 2006).

For the purposes of assessing progress toward the target to achieve by 2010 a significant reduction in the current rate of biodiversity loss, biodiversity loss is defined as the long-term or permanent qualitative or quantitative reduction in components of biodiversity and their potential to provide goods and services, to be measured at global, regional, and national levels (decision VII/30, paragraph 2 of Strategic Plan). The “current” rate is taken to be the rate in 2002, when the Strategic Plan was adopted.

Glossary

Disturbance regime The nature, frequency and intensity of events or agents that cause a temporary or permanent loss of biomass.

Fynbos Shrub and heath vegetation type that is characteristic of the Cape Floral Kingdom in South Africa.

Herbaceous species Plant species that do not form woody tissue, and are often much shorter lived than woody species such as trees and shrubs.

Net primary production Plant photosynthesis less plant respiration.

Species diversity Species richness adjusted to account for abundance.

Species migration For plants this refers to the directional change in a species geographic range over time, as opposed to the seasonal bi-directional movement of individual organisms such as migratory birds.

Species range The geographic area within which a species can be found.

Species richness The number of species recorded for a particular area, with each species given an equal weighting.

Observations

One of the most general apparent relationships between climate and the diversity of species is reflected in increases in species richness from each pole toward the equator, a pattern that has very few exceptions (Hillebrand, 2004). The general term diversity used here indicates a measurement of the number of species which exist in a particular area, a measure more correctly termed species richness. The measurement of species richness quantifies the number of species recorded for a particular area, with each species given an equal weighting. Strictly speaking, species diversity is a measure that accounts both for species richness and different species' abundances (termed equitability), but the terms are often used interchangeably. Because data on species abundances globally are limited and, at best, may only include species lists, with some notional area of observation, this general analysis will substitute species richness for species diversity. The latitudinal gradient identifies a potentially important role for climate in limiting diversity, mainly through climate control of energy availability (temperature and radiation), but several other factors are also seen as important in explaining the pattern, including the role of spatial area, evolutionary time, and ecological factors (species interactions).

Species to Area Relationships

The horizontal surface area within which species are counted plays a critical role in quantifying species richness. This relationship has been termed one of the few fundamental laws of ecology (Lawton, 1999). Rosenzweig (1995) provides an extensive account and examples of the relationships between species richness and area. One example is presented to illustrate the typical nature of the relationship for the flora of the British Isles (Figure 1). Figure 1(a) shows the relationship for

untransformed scales, with a particularly notable and rapid increase in species richness following small initial increments of area. Figure 1(b) presents the same data for log-transformed scales, in which the relationship is linear. Figure 1(b) indicates that the rapid increase in richness to about 1000 species occurs as the scale of observation increases from 0.1 ha to 1 million ha (10,000 km² or 100 km × 100 km).

All spatial scales contain data of ecological interest; however, in the context of the climatic control of diversity, the small areas are of less direct relevance. For example, the smallest scale in Figure 1 of 0.1 ha (approximately 32 m × 32 m) is too small to include many individual plants such as mature trees, and this would also apply to data for animal species that are often locally rare (e.g., birds and mammals). This is therefore a sampling problem. The problem lies in deciding when this species to area relationship might indicate a primary control by climate, over and above any problems of sampling. It can also be envisaged that if an area under study has high landscape diversity, or habitat heterogeneity (e.g., it is a flat plain vs. a mountainous area), then this will also influence the species to area relationship, as has been reported (Cowling *et al.*, 1994; Baldi, 2008). Such environmental features are incorporated into general species lists and cannot easily be dissected out. Nonetheless, a comparison of species richness with scale for the British Isles and the fynbos of South Africa (Figure 2) indicates very large differences in diversity, but the untransformed scale (Figure 2(a)) shows that the differences between the two floras decrease much more slowly above areas of approximately 2 × 10⁷ ha (2 × 10⁵ km² or 450 km × 450 km). It is well known that fynbos diversity has been strongly enhanced by landscape heterogeneity (Linder *et al.*, 2010), and therefore the decreasing divergence in trend between these two data sets above 450 km × 450 km indicates a useful order of scalar magnitude for comparing floras in the context of examining climatic control.

Figure 1 Species richness of the British Isles: (a) untransformed axes and (b) log-transformed axes.

Time Dependency

The species composition of an area endures changes with time, through mortality, disturbance, and migration. Disturbance of a moderate frequency can maximize species richness, the so-called “intermediate disturbance hypothesis,” but analysis shows that this pattern is far from universal (Mackey and Currie, 2001). Large-scale extreme disturbances produce landscapes in various stages of recovery, accompanied by increasing diversity. An extreme disturbance event was the 1883 volcanic eruption which completely denuded the flora of the Krakatau Islands. A recent enumeration of higher plant species (Figure 3; Whittaker *et al.*, 1990) showed a monotonic increase in the species complement during the past 100 years. It is clearly not possible to assess the final species richness of

these islands until the species complement reaches some asymptote. This is an example of primary succession (where the biophysical environment establishes *de novo*) and is extreme in the context of contemporary time scales, although smaller-scale recoveries from natural disturbance and larger-scale recoveries from human disturbance are current widespread features. Human disturbance is generally considered to deplete species richness and push natural ecosystems to early stages of secondary succession (where the biophysical environment, e.g., soil structure, remains intact); however, over the large spatial scales considered for this article, it is assumed that species richness has not yet been markedly depleted by human activities.

The last ice age was the most recent natural global-scale disturbance to the biosphere. At that time, glaciers spread over

Figure 2 Species richness of the British Isles compared with the fynbos of South Africa: (a) untransformed axes and (b) log-transformed axes.

the large areas of North America, Europe, and Russia and clearly removed all species in their paths. The cooler glacial climate, in addition to the spread of glaciers, led to the equatorial migration of most species, especially in the Northern Hemisphere. However, in Europe, for example, the Alps prevented significant migration further toward the equator, with significant extinctions at this barrier. The climatic amelioration to the current interglacial climate reversed the process, which occurred during the ice age. However, reduced richness follows as a consequence of the irreversible species extinctions. The degree of this loss of richness can be addressed in part not only from paleoecological information but also from comparative subcontinental biogeographic and phylogenetic studies (Wiens

and Donoghue, 2004). An example of the latter is that of eastern Asia and eastern North America, where eastern Asia shows regional richness approximately 1.3 times higher than eastern North America after the effects of climate are accounted for (Ricklefs *et al.*, 2004), and may be due to greater latitudinal connectivity between temperate and tropical floras in eastern Asia, which lowered regional extinction rates under glacial-interglacial climatic changes. These long-term effects, and the shorter-term effects of disturbance, are incorporated in regional assessments of species richness. Despite this, the effect of contemporary climate on diversity remains relatively strongly discernible within these regions, with richness positively related to winter temperature.

Figure 3 Measurements of species richness on the Krakatau Islands, Indonesia, since the major volcanic eruption of 1883. Subsequent and lesser volcanic events are also indicated by arrows.

(a) Species area curves for six groups of countries (42 countries in total) selected for similarity of temperature and NPP, using data for country area and mean country NPP. (b) Relationship between c (plant species per square kilometer) and NPP ($\text{gC m}^{-2} \text{yr}^{-1}$) for 42 countries selected for similarity of NPP, mean annual temperature, and geographical location; for an additional 86 countries (---); and for all 128 countries combined (....), where $\log_{10} c = 0.01233 \times \text{NPP}(\text{gC m}^{-2} \text{yr}^{-1}) - 0.01475$, $r^2 = 0.58$. Reproduced from Kelly CK and Woodward FI (2008) Responses of global plant diversity capacity to changes in carbon dioxide concentration and climate. *Ecology Letters* 11: 1229–1237, with permission from Wiley.

Observations by Area

The impacts of area on species enumeration and on the relationship between climate and species richness are well illustrated (Figure 4) using data synthesized by Kelly and Woodward (2008). They showed that plant species richness per square kilometer is significantly positively related to net primary productivity (NPP), a measure that reflects climatic drivers of plant production (temperature and water availability). Previous work also showed that per area absolute plant species richness is lower in colder environments. Such observations conform with observations and modeling by Woodward (1987), which demonstrate a decreasing capacity for species survival with decreasing temperatures.

Global-Scale Observations

The global-scale distribution of species richness is increasingly better documented, and a comprehensive atlas, for example,

is available for download at: <http://quin.unep-wcmc.org/resources/publications/biodiversityatlas/presspack/index.htm>

Species Richness and Latitude

The first cut at assessing species richness has traditionally been conducted by latitude. This spatial variable includes many environmental features, particularly solar radiation receipt, day length, and temperature, but it is a useful variable for assessing broad-scale controls on vegetation. Figure 5 indicates a spread of richness with latitude. In the northern latitudes, the maximum observed richness decreases with increasing latitude. A similar relationship can be defined for the Southern Hemisphere, except that there are significant exceptions. These cases include the southeast coastal region of Brazil, extending from Porto Alegre (Figure 5, Brazil 3) in the south through Rio de Janeiro (Figure 5, Brazil 1) to Vitoria (Figure 5, Brazil 2) in the north. Additional sites of high diversity have been sampled for South Africa (The Cape) and

Figure 5 Changes in species richness with latitude. Details of the identified sites are discussed in the text. Data from Barthlott W, Lauer W, and Placke A (1996) Global distribution of species diversity in vascular plants: Towards a world map of phytodiversity. *Erdkunde* 50: 317–327.

Figure 6 Changes in species richness with annual mean temperature.

Australia (Perth). The sampling scheme for global diversity does not cover all areas of high diversity, but these five sites in the Southern Hemisphere and, to a lesser extent, the Mediterranean region in the Northern Hemisphere clearly indicate that areas of unusually high diversity do exist. These areas are defined as unusual because they seem outside the typical latitudinally dependent maximum extents of diversity. Using the increasingly resolved global data set for plant species richness, it has been found that potential evapotranspiration (a measure of energy availability), the number of wet days per year, and measurements of topographical and habitat heterogeneity are powerful predictors of species richness (Kreft and Jetz, 2007). This analysis explains a remarkably high 70% of the global variation in plant species richness, and reproduces the latitudinal gradient in richness. Only one major exception is found – that of the Cape Floristic region in South

Africa, which has about double the expected number of plant species! Like plant species richness, animal species richness shows a strong latitudinal trend that could indicate co-dependence on plant species richness, direct mechanisms driven by climate, or a combination of these (Midgley *et al.*, 2010).

Species Richness and Climate Temperature

The observations in sections Observations by Area and Species Richness and Latitude suggest that cooler and drier climates are less diverse. This same result is observed at the global scale (Figure 6), when mean annual climate (for the 1970s and sampled at a scale of 10,000 km²) is compared with a map of standardized species diversity (also adjusted to a 10,000 km² scale) (Barthlott *et al.*, 1996). At mean temperatures greater

than approximately 5 °C, species richness both increases markedly and becomes significantly more variable between individual sample points. The high-temperature, low-diversity sites are typically deserts or very arid, where it is clear that water supply is the critically limiting factor for plant survival. The areas of unusually high diversity in South Africa and Brazil are clear extremes in the temperature relationship, but the other sites shown in [Figure 5](#) are not distinct.

Precipitation

The relationship between richness and temperature is not simple and is also influenced by other climatic features, particularly precipitation. In contrast, 42% of the variance in richness ([Figure 7](#)) is accounted for by a linear correlation between richness and annual precipitation. This association defines the obvious observation that diversity increases toward the tropics and is highest when warmth and high precipitation coincide. Four of the five recognized areas of high diversity remain as outliers from the remainder of the data set.

Net Primary Productivity

Precipitation is often taken as a surrogate for vegetation productivity in order to investigate any relationships between productivity, usually NPP and diversity or richness. Although precipitation exerts a large effect on NPP, this is not the only influence; other climatic features such as solar radiation receipt, day length, growing season temperature, and annual minimum temperature can exert significant effects on NPP ([Woodward, 1987](#)). Simulation models of NPP typically incorporate the effects of all these climatic variables to provide an integrated effect, seen as simulated NPP ([Woodward et al., 1995](#)).

In diversity studies, productivity is used and assessed in two different ways. For small field plot experiments, productivity is measured directly as the accumulation of biomass and is generally viewed as a consequence of diversity. On larger scales, intensive measurements of NPP are impossible,

and in this case productivity is generally simulated by some type of process model; it is more appropriate to consider diversity as a consequence of simulated NPP because this simulated value accounts for all variations in climate but is generally independent of any aspects of diversity.

In this case, a typical process model ([Woodward et al., 1995](#)) has been used. Annual NPP is the net fixation of carbon into plant biomass, after plant respiration is decremented from annual photosynthetic fixation. In ecological terms, NPP is a measure of the rate of production of biomass (usually over an annual interval) and which is available for consumers and for creating new plant structure. Simulation models can often provide more accurate estimates of annual production, particularly in multiseasonal environments, which would require many harvests for accurate assessments of NPP in the field.

Simulated NPP provides a tighter fit than annual precipitation to the observed variations in species richness at the global scale ([Figure 8](#)). However, three of the high-diversity sites are notable outliers from the line of best fit. The site in South Africa is the most extreme, as previously recognized, with a very high richness associated with a low NPP. Much of this area of vegetation is known as fynbos, a heathland on very impoverished soils. A further analysis of species richness in this area, and for the whole of southern Africa northwards to a latitude of 15° S, has been completed by [O'Brien et al. \(1998\)](#). In this case, only the richness of woody species (native trees and shrubs with heights of greater than 1.5 m) was considered. Woody species richness is very strongly correlated with NPP ([Figure 9](#)), and the high-diversity site of [Figure 8](#) (arrow in [Figure 9](#)) is not now distinguishable from the general trend. The high richness at this site is clearly due to herbaceous species and subshrubs, and explanations for their high diversity must be sought in factors other than current climate, such as disturbance frequencies and types, the low nutrient status of the soils, and factors related to biogeographic history, particularly rates of speciation and probabilities of species' migrations.

Data from O'Brien EM, Whittaker RJ, and Field R (1998) Climate and woody plant diversity in southern Africa: Relationships at species, genus and family levels. *Ecography* 21: 495–509.

Theories

The strong latitudinal gradient in species richness has long been recognized and has stimulated a wide range of theories to explain the observations. At the same time, relevant new data sets are continually being produced and analyzed in new ways. These data have been used to derive empirical or observational hypotheses about the controls of richness, mainly by seeking statistical support for relationships between diversity and multiple explanatory variables, with the recognition that correlation does not imply causation. In principle, an empirically derived hypothesis is supported if it can be tested using first principles. However, nature does not yield its secrets so easily, and ambiguity seems to be the rule in that it is often difficult to

differentiate between different theories and hypotheses when the differences in their consequences are often by degree rather than absolute. It is also clear that several explanations of what determines diversity patterns may be valid and not mutually exclusive, but rather interact to yield the global, regional, and local patterns observed. This article presents current theories and hypotheses which address the relationships between climate and species richness.

Narrowing the Questions Using Observations

The defined area for observing species richness exerts a major impact on the quantity of richness. A less obvious, but also

important, consideration is that the context within which areas exist requires consideration. For example, **Figure 10** indicates that islands show a greater increase in richness with area than do areas of the same size but nested within a region with no dispersal and migratory barriers. This observation highlights that the species richness of any area is the net result of species immigration, extinction, and evolution. For an island, the rate of species immigration will be less than that for an area embedded in contiguous land surface, and as a consequence the island richness will be less because local species extinctions are not readily matched by migration. Such insights have led to the theory of “island biogeography.” With increasing island size, the potential for the arrival, establishment, and persistence of migrants increases, and so extinctions will be fewer and richness will increase to values similar to

that of the contiguous land sites. This has also been elegantly demonstrated for islands artificially created through the damming of the Vaal River in South Africa (Dean and Bond, 1990). An important contemporary corollary to the change in diversity with area is that any process, such as human land clearance, which effectively creates isolated fragments will inevitably lead to a loss of diversity.

The response shown in **Figure 10** also scales to larger areas (**Figure 11**). In this case, the species-to-area relationship for the British Isles is much flatter than that for separate provinces and continents, from New Zealand, at the smallest, through Australia and Africa to the world. The flattest curve for the British Isles will include some component due to the net balance of extinctions and immigrations, plus a capacity for species to migrate throughout the British Isles, thus evening

Figure 10 Changes in species richness with area for islands and mainland California.

Figure 11 Changes in species richness with area within the British Isles (solid line) and between different floras (dashed line).

out, to some degree, the scale dependence of species richness. Different provinces and continents may be more or less isolated for immigration and also possess species complements determined by local effects such as habitat heterogeneity, historical effects such as past ice ages, and even longer-term speciation events. Climate will play and will have played a part in conjunction with these influences, therefore, in the contemporary species richness of these large areas. The climatic range of the British Isles – for example, in temperature and precipitation – is small compared with that for a continent, but the range of soil conditions is wide, from fertile alluvial soils to very low-nutrient bogs and chalk downs. Therefore, the species area curve (**Figure 11**) for the British Isles also displays the influence of habitat diversity, particularly soil nutrient status on species richness. In this case the effect is small, and suggests, therefore, that latitudinal gradients in soil nutrient conditions may not play a major role in determining the gradients of richness seen, for example, with latitude (**Figure 5**).

Observations by Rapoport (1982) introduced an alternative twist to the understanding of the latitudinal pattern of species richness. Rapoport noted that, on average, the geographical range of species increased with latitude, and surmised that there are fewer species at high latitudes and they are on average more widely dispersed. Subsequent analyses (Gaston, 1999) have indicated that this relationship is neither universal nor simple. However, there is some consistency in the pattern from the tropics to high latitudes, particularly in the continental landmasses of the Northern Hemisphere, although the pattern is far weaker at the global level, possibly reflecting different biogeographical processes in the Northern and Southern Hemispheres (Ruggiero and Werenkraut, 2007).

Theories and Hypotheses

Theories and hypotheses for explaining the documented decline in diversity with latitude are based on one or more of the following fundamental controls:

- Competition for necessary resources.
- Gap creation in vegetation by disturbance.
- Energy availability.
- Climatic extremes.
- History.

Competition

The competitive exclusion of species, which require the same resource, has been a theoretical underpinning to much of ecology, not just the climate control of diversity. Originating from simple experiments, it has proved easy to demonstrate the importance of competition in species interactions in response to changes in climate and in very small-scale experiments. It has not been so easy to demonstrate the importance of competition in defining the distributional limits of species on a larger field scale. Often, it seems that environmental heterogeneity in time and space can allow coexistence to occur, apparently circumventing direct competition for resources (Huston, 1979). However, competition is still considered an important mechanism in controlling survival and

therefore diversity, but it does not appear to be easy to demonstrate competition in action.

It does seem that if competition is to play a major role in the control of species distributions, then it must do so as a secondary action to the primary action of climate. For example, consider the distribution of a boreal forest species in the cold of the high latitudes and a tropical species from the warmth of low latitudes. If competition plays a role in these distributions, then it must favor boreal species at high latitudes and tropical species at low latitudes (i.e., competition is latitude dependent). Competition can only be latitude dependent through its impact on species' interactions, and this would either be through a climatic dependency of species' contemporaries or through historical responses. Therefore, it seems that competition is an integral and probably secondary part of a climatic control of diversity.

Disturbance

Creating gaps in vegetation or clearing vegetation above ground by disturbance appears to provide a mechanism for avoiding direct competition and for providing bare ground and the opportunity for new species immigration. If some species are long lived and can survive disturbance events, then they can co-occur with shorter-lived species, which depend on disturbance, and therefore diversity can be maintained. If the rate of disturbance changed systematically with latitude, then this could provide an explanation for the decline in diversity with latitude. However, the major global disturbance agent, wildfire, has been shown to peak in frequency at midlatitudes (Midgley *et al.*, 2010), though this affects ecosystem structure more than it does biodiversity. It has been suggested that midlatitude grassland fires reduce the potential global area of dominance of trees by a considerable fraction (Bond *et al.*, 2005), but ancient fire-maintained grasslands have accumulated significant levels of biodiversity in low-growing plant growth forms such as bulbous plants that tolerate fire. Nonetheless, there is some evidence that at local and regional spatial scales, an intermediate level of disturbance supports maximum diversity (Huston, 1979).

Energy Availability

Hutchinson (1959) suggested that the availability of energy may constrain species diversity. Studies have since shown strong positive correlations between diversity and evapotranspiration, which is often taken as a surrogate for both energy and NPP. **Figure 8** shows a clear relationship between NPP and species richness, but in this case climates with high energy inputs from solar radiation but low precipitation will lead to low NPP. O'Brien *et al.* (1998) describe the same response where water availability tempers a direct response of diversity to energy. Therefore, the relationship between diversity and energy is not simple, whereas the relationship between NPP and richness is in general quite linear (**Figure 4**). However, the mechanistic nature of the relationship is quite unclear in either case.

In some cases, particularly in small-scale experiments with variable resource supply, NPP and diversity are often negatively correlated, with just a small number of rank-growing species dominating energy capture and production. Such a

response is opposite to that observed at the larger, global scale (Figure 8) and, based on Figure 1(a), indicates that climatic control of diversity is difficult to determine when the area of observation is on the steeply rising curve of the species–area relationship. Nevertheless, small-scale experiments have often influenced ideas at the global scale. It is generally considered that sites of high NPP are highly competitive, with only a small number of dominant species. However, highly productive tropical forests are also highly diverse in terms of both species and vegetation structure, even with limiting soil nutrient resources. The vegetation canopy may have many strata, with different species in each strata. High NPP requires a high supply rate of resources, particularly soil nutrients, water, and solar radiation, with no significant temperature limitations. On low-nutrient soils, the vegetation retains the majority of the soil nutrients, whereas water is in abundant supply. In these forests, turnover of plant parts (leaves, twigs, and small branches) is quite rapid, as is the decomposer system and thus also the rate of nutrient recycling. Therefore, the high NPP goes hand in hand with a high requirement and supply of nutrients to all component species. This appears to be the major mechanism by which high NPP can sustain high diversity. In addition, large areas of forest also transpire large quantities of water vapor, which returns as rain and also increases local cloudiness. The high NPP vegetation therefore exerts some control over its own climate, making it more equable and moderating energy supply.

It is clear that the energy availability, as represented by evapotranspiration, provides a good prediction for species richness globally, and this has been linked with NPP, which is modeled as peaking at low latitudes. However, the widely accepted view that NPP increases toward the equator has been questioned recently (Huston and Wolverton, 2009), a development that is likely to call into question many assumptions about the mechanisms that underpin the climate–species richness relationship. This development may well provide a

new impetus to the question of climate control of species diversity.

Climatic Extremes

Climate appears to influence diversity by a range of mechanisms such as by influencing turnover times of soil nutrients and through constraining the length of the growing season. However, it is also well established that species have a range of minimum temperature tolerances which is much greater than the range of maximum temperature tolerances (Woodward, 1987). At the global scale, absolute minimum temperatures in vegetated areas of the world vary from approximately -80 to 20°C and species are appropriately adapted to the local absolute minimum temperature, even if this occurs only every 10–30 years. Therefore, minimum temperature tolerance increases with latitude. There also appears to be a cost involved in possessing a particular degree of temperature tolerance, with the cost probably reducing growth capacity and competitive ability compared with those of species possessing a lower minimum temperature tolerance (Woodward, 1987). As the absolute minimum temperature decreases, so also does the number of species that can survive (Woodward, 1987).

The absolute minimum temperature decreases with latitude; therefore, this mechanism alone could account for the latitudinal trend in species richness (Figure 5), if fewer species have evolved the capacity to endure increasingly lower temperatures. However, this does not account for the absence of low-temperature-tolerant species from warm climates; in addition, low absolute temperatures are associated with shorter and cooler growing seasons. Therefore, the impact of climatic extremes on richness almost certainly occurs in parallel with other climatic limits.

It is possible to use simple models to investigate the impacts of changes in absolute minimum temperature and competition on distribution and diversity. Figure 12 shows a typical output of a model in which species are designed

Figure 12 Simulated changes in species richness with absolute minimum temperature, without competition (solid line) and with competition (dashed line).

Figure 13 Simulated occurrence of a species with a minimum temperature tolerance to -35°C , without competition (solid line) and with competition (dashed line).

with the capacity to survive to predetermined minimum temperatures but have the capacity to survive at all higher temperatures. In a second case, the competitive ability of the species declines as temperatures increase above the low temperature cutoff for survival. In cases of both competition and no competition, richness increases with temperature. However, in the simulation with competition, diversity increases less at temperatures higher than -20°C . This occurs because competition excludes those species with the lowest temperature tolerances from the highest temperatures. This does not occur in the simulation with no competition.

Figure 13 illustrates the case for a species with a minimum temperature tolerance to -35°C . Competition exerts no effect on abundance to -30°C , but at higher temperatures the abundance or occurrence of this species decreases consistently to zero at -5°C . Without competition, there is still a reduction in the occurrence of this species with increasing temperature, and this occurs simply because the chance of occurrence decreases as the pool of species increases with temperature. **Figure 12** demonstrates that richness decreases with decreasing temperature; however, the occurrences of the tolerant species increase, in line with the suggestion by Stevens (1989).

The model is simple but it readily predicts changes in diversity with temperature and also indicates that a reduction in richness will be associated with an increase in the abundance of species. Both examples (**Figures 12** and **13**) also indicate that the effect of competition is primarily one of degree, and therefore it will prove very difficult to differentiate between direct competitive effects and a simple lottery model as both temperature and the species pool increase.

Biogeographic History

It appears that competition, disturbance regime, energy availability, and climatic extremes can all influence the way in which climate affects species diversity. It also seems likely that

we cannot readily differentiate between these controls at the global scale. However, none of the models are capable of explaining the sites that are outliers in the general relationships between richness and latitude (**Figure 5**), temperature (**Figure 6**), precipitation (**Figure 7**), and NPP (**Figure 8**). Further analysis indicates that these areas all have high frequencies of endemic species, and at the global scale species richness is positively correlated with the degree of endemism. The high degree of endemism in the fynbos of South Africa (see Species Richness and Latitude) and kwongan vegetation of South West Australia appears to be strongly correlated with the degree of soil infertility. In these areas, richness decreases with increasing soil fertility. However, both landscapes are very infertile and ancient in geological terms, and it seems likely that the infertile soil serves as a barrier to immigrants. The coastal Atlantic forests of Brazil are isolated from other areas by an inland mountain chain, indicating another method of limiting migration and cross-fertilization and enhancing species richness.

Processes associated with history and regional landscape structure seem to be the most parsimonious explanations for the high species richness in these areas. In the Cape floral kingdom of South Africa, there are more than 500 species in the genus *Erica* (Bond, 1989). The species are structurally very similar and it seems unlikely that their ecological characteristics are very different. Such situations suggest that the species concept is not an ideal measure of richness, particularly of ecological richness. The indicated areas of high diversity (**Figure 5**) certainly indicate high taxonomic richness, but is this relevant to the climatic controls of richness? A growing body of work has identified the strong role of climate history, particularly during the Pleistocene (ice ages) on species diversity, and this is providing insights into these species diversity outlier regions. Analysis shows that these regions may have escaped exposure to the extreme climatic shifts that were experienced over much of the rest of the planet during the

Pleistocene (Jansson, 2003), allowing species to diversify with low rates of extinction.

Experiments

Numerous experiments have investigated the relationship between species richness and productivity. However, through practical necessity, these experiments have been carried out on a small scale, well within the range of rapidly increasing richness with area, as shown in Figure 1. Tilman (1999), a major contributor to the productivity–diversity debate with Grime (1997), has indicated that this understanding, developed from scales where sites are populated from the same regional species pool, is inappropriate for addressing larger-scale latitudinal patterns. Although this scale may not be appropriate for the larger-scale considerations discussed in this article, it is interesting to explore briefly its possible relevance.

One experimental approach which can, in part, be used to address the relationship between diversity and climate is that of a herbaceous productivity–diversity multisite experiment distributed across Europe (Hector *et al.*, 1999). Eight sites were distributed between 39° N and 64° N latitude and 8° W and 27° E longitude. In all cases, these grassland experiments were seeded from a bare soil state with a known number of species, from one to at least eight. At all sites, aboveground biomass, a measure of productivity, increased with species richness, in keeping with the correlation shown in Figure 8. Although the expected reduction in biomass with short growing season (either through drought or low temperatures) was clearly demonstrated, it was not possible, in a 2-year experiment, to determine the effects of climate on the equilibrium species richness of the plots. More recently, strong evidence has emerged that there appears to be no relationship between species diversity and productivity at this level of spatial scale (Huston *et al.*, 2000). Indeed, a large number of experiments have been completed since the 1990s, and a meta-analysis of the results is now revealing that biodiversity effects on aspects of ecosystem function vary between ecosystem types, show idiosyncratic patterns (Schmid *et al.*, 2009), and are therefore very difficult to generalize.

Genome Size

In addition to resolving the mechanisms by which climate controls species richness, it is also important to be predictive. For example, given a particular climate, what will be the diversity and what will be the characteristic behavior of the local species? An alternative question is, given a particular metric of a species, where might the species be distributed naturally and in how diverse a mixture of species? These questions cannot be resolved; however, there has been a continued interest in relating the size of the nuclear genome of a species in this way (Grime, 1998). Relationships between genome size and critical climatic tolerances of frost resistance, precipitation supply, and growing season have been found, as have relationships between genome size and plant growth dynamics. The understanding of this issue has developed with the proposal of the “large genome constraint” hypothesis. In

essence, it is now emerging from the data available that plant species with large genome sizes are constrained in terms of their photosynthetic rates, their diversification rates are lower, and they have restricted ecological ranges (Knight *et al.*, 2005).

Conclusions

The impacts of climate on plant biodiversity are best studied on the large scale, on the order of hundreds of kilometers. This approach escapes the currently insoluble problems of disentangling the effects of scale, landscape structure, and negative small-scale relationships between productivity and diversity. Freed from these constraints, the large-scale nature of the study indicates that observations and correlations are the primary mechanisms for understanding the processes by which climate controls diversity. The processes are still not fully clear, but primary productivity, disturbance, length of the growing season, and competition all appear to play important roles. There are some locations where species richness is much larger than the average that would be expected based on current climate. These areas are rich in endemic species which have probably originated and persisted because of migratory and reproductive barriers, and benefited from less variable Pleistocene glacial/interglacial climatic shifts. In these areas, it is likely that species differ very little if at all in ecological characteristics, and reflect a globally rare phenomenon of species accumulation by extraordinary diversification and persistence that partly reflects climate history. The widely accepted view that NPP increases toward the equator has been recently questioned, a development that should provide a new impetus to the question of climate control of species diversity.

Glossary

Combating desertification Activities specifically aimed at prevention and/or reduction of land degradation, rehabilitation of partly degraded land, and reclamation of desertified land.

Desertification Land degradation in drylands resulting from various factors, including climatic variations and human activities.

Dimensions of desertification The interactions and feedbacks of meteorological, ecological, and human components of land degradation.

Dryland Development Paradigm A conceptual framework to aid in understanding the complexity of desertification and dryland development by identifying and synthesizing those factors important to research, management, and policy communities.

Drylands Arid and semiarid croplands, pastures, rangelands, and subhumid woodlands where the index of aridity is less than 0.65; they cover more than two-fifths of

the land surface of the globe, and are home to 35% of the human population.

Index of aridity Ratio of mean annual precipitation to mean annual potential evapotranspiration.

Land The terrestrial ecosystem that encompasses soils, vegetation, other biota, and the ecological, biogeochemical, and hydrological processes that operate therein.

Land degradation Reduction or loss of the biological and economic productivity and complexity of terrestrial ecosystems, including soils, vegetation, other biota, and the ecological, biogeochemical, and hydrological processes that operate therein.

Myths of desertification Controversy stemming from failure to consider all dimensions (meteorological, ecological, and human) of the problem of land degradation, and the alarmist tone connoted by the word “desertification,” which incorrectly suggests the action of deserts “moving” across a landscape, engulfing fertile lands and leaving starving people in their wake.

Introduction

Land Degradation in Global Drylands

Water covers 70% of the Earth's surface, with the remaining 30% covered by land. In turn, more than 40% of this terrestrial land area is classified as drylands, which exist on all continents, but are most widespread in Africa and Asia (Figure 1). Drylands are home to 2 billion humans or 35% of the total population of the Earth, 90% of whom reside in developing countries. The fate of many of these people is ultimately dependent on the availability (and efficient utilization) of natural resources, for example, water, soils, plants, and wildlife. However, unsustainable use of water, poor agriculture practices, deforestation, and climate change have resulted in the degradation of extensive land areas of drylands.

It is estimated that approximately 6–12 million km² (~10–20%) of all drylands suffer from serious land degradation. This directly impacts the food security, health, material needs, and other aspects of the livelihoods of 250–300 million people (Millennium Ecosystem Assessment, 2005; Reynolds *et al.*, 2007a). Many more drylands are potentially at risk, especially as populations continue to grow. Dryland degradation currently costs developing countries approximately 4–8% of their gross annual domestic product (EMG, 2011).

Although present in all biomes, land degradation in drylands is generally referred to as “desertification.” Desertification has occurred over large areas in Asia, the Mediterranean, Africa, Oceania, and the Americas, involving the loss of the structural and functional integrity of soils, vegetation, other biota, and those ecological, biogeochemical,

and hydrological processes that operate therein. Typical consequences include the elimination or major reduction of the endemic plant and animal species, a decrease in the infiltration of precipitation into the soil, inefficient nutrient cycling, water erosion, and increases in soil salinity (Figure 2(a–i)). These changes have direct impacts on the human populations who rely on these ecosystems for their livelihoods.

The Creation of Deserts: Reality versus Myths

Deserts on the Move!

The topic of desertification has evoked much confusion and controversy over the years (Reynolds and Stafford Smith, 2002). Perhaps the number one culprit is the alarmist tone connoted by the word “desertification.” The French forester Andre Aubréville is credited with coining the term desertification in 1949. Aubréville's usage was in the context of the indiscriminate felling and burning of forests and woodlands in subhumid Africa and the accelerated soil erosion that ensued: that is, what he and his colleagues saw as the “creation of deserts.” It evokes an image of deserts literally moving across a landscape, engulfing fertile lands and leaving starving people in their wake. These popular images have their roots in a series of papers written in the 1930s by the British forester Stebbing, who used titles such as “The encroaching Sahara” and “The man-made desert in Africa.”

In the late 1970s, desertification was first brought into the public spotlight when the United Nations (UN) announced that more than one-third of the terrestrial land surface of the

Figure 1 Drylands of the globe as defined by the aridity index, the long-term mean of the ratio of an area's mean annual precipitation to its mean annual potential evapotranspiration. This map is based on data from United Nations Environmental Programme Geo Data Portal. Global area based on Digital Chart of the World data (147,573,196.6 km²). Data presented in the figure are from the Millennium Assessment core database for the year 2000. Data from Millennium Ecosystem Assessment (2005) *Ecosystems and Human Well-being: Desertification Synthesis*. Washington, DC: World Resources Institute.

globe was "at risk of desertifying". Africa was identified as a particularly serious region of concern. This coincided with a series of major droughts in sub-Saharan Africa that, when combined with weak economies and civil strife in the region, resulted in widespread famine and the deaths of millions. The UN held a high profile Conference on Desertification in Nairobi in 1977 and adopted a Plan of Action to Combat Desertification (PACD) "to curb this onslaught."

The droughts and famines of the 1970s served to reinforce the impression that massive deserts were being formed in drylands. The word "desertification" was applied indiscriminately, even for climatic regions that were natural deserts. To varying degrees, this myth persists to this day, especially in the general news media and also in some policy and scientific circles. Provocative news articles with titles such as "Droughts, Deserts and Death," "Sahara Jumps Mediterranean into Europe," and "Greedy Sahara Devours Land Along Its Border" certainly evokes emotions but not necessarily reality (Reynolds and Stafford Smith, 2002).

The root problem is that land degradation is not a simple phenomenon. One key misunderstanding stems from the fact that drylands are fundamentally fragile ecosystems and, hence, highly susceptible to disturbance. A decrease in vegetation cover due to a short-term response to drought, for example, those captured by satellite images in the Sahara, and soil degradation (a longer-term or permanent response resulting from chronic disturbances) are distinct and not necessarily

related phenomena. The former is reversible when the drought is over, but severe land degradation may not be so. Satellite images of the dynamics of plant cover on the margins of the Sahara desert have clearly demonstrated that its "boundary" is quite dynamic (Figure 3): There are periods of "expansion" and "retreat," which coincide with the severity and duration of droughts. Another example of short- versus long-term dynamics is given in the section Dimensions of Desertification.

A Stakeholders Perspective

To a large extent, the degree to which land is considered degraded in a particular area depends on the priorities of local users. Clearing native woodland in order to grow crops may increase soil erosion and negatively impact the economic business of firewood collection, but increase food production. With respect to land degradation, changes in the characteristics of soils, water, and vegetation do not have a linear relationship to the productivity potential of the land. Reynolds and Stafford Smith (2002) provide an example to illustrate how different stakeholders may view land degradation through the lens of their particular needs and priorities.

Imagine a cattle ranch in central Mexico, where a herd of cattle is grazing in a pasture that has a large number of erosion gullies (e.g., Figure 1(b)). Whereas one might deduce that these gullies are the result of overgrazing, which removes plants and exposes the soil to water and wind erosion

Figure 2 Images of land degradation in drylands. (a) Plowed field in Salar de Uni region of southern Bolivia, leaving soil highly susceptible to wind and water erosion. (b) Erosion gullies being formed in cultivated landscape north of Port Elisabeth, South Africa. (c). Cattle and sheep disturbance around a watering hole in southern New Mexico. (d) Terracing of hillsides on Loess Plateau (China) to curb soil erosion. (e) Mixed-use cultivation and goat grazing in village of La Amapola, Mexico. (f) Woody plant encroachment in native grasslands of central Argentina and dust storm from resulting exposure of sensitive soil surface. (i) Wood gathering in Ivory Coast, Africa. All photos by author except (f) (courtesy of R. Distel), and (i) (courtesy of UNESCO-MAB).

(which is usually true), alternative stake-holder views of these gullies are possible (Figure 4):

1. the erosion gullies are the result of natural phenomena (wind and water);
2. in some landscapes gullies, whether natural or induced by overgrazing (and depending on the severity and length of time since forming), may have no effect on what matters in terms of human values (such as meat production);
3. although the erosion gullies may not connote a loss in meat production on this ranch *per se*, they may be creating salinity problems downstream from the ranch or threaten the survival of endemic plant species; and
4. even if the gullies are the direct result of overgrazing, there is room for debate as to whether the root cause is overstocking by the rancher, a product of the land tenure system of this area, climate-driven, or an indication of broader institutional problems (or possibly any combination of these).

An ecologist will view erosion gullies as representing a loss of ecosystem structure and function, for example, the ability of

the soil to retain water, nutrient cycling, long-term soil stability, and reduced forage production. Although true, this may resonate with a local rancher only if it has a demonstrable impact on his beef production. Of course, broader concerns for appearances or genuine environmentalism may also arise, but the rancher would unlikely invest in gully control on these grounds alone unless, for example, it was linked to an environmental accreditation scheme for the ranch. Gullies could also matter to a local tourist operator who finds that eco-tourists are put off by the appearance of environmental damage. Simply put, different stakeholders may see this problem differently.

The Dryland Syndrome

Reynolds *et al.* (2007a) posited that drylands tend to have a common nexus of environmental, ecological, and social-economic characteristics. They termed this as “dryland syndrome.” Some of the main features of the dryland syndrome are presented below.

Figure 3 Extent of the Sahara Desert, shown in terms of annual deviations from average size defined by a 200-mm rainfall isohyet extending to the north of 25° N. Calculations based on rainfall data collected at 141 locations throughout West Africa (Rain Obs), from Meteosat satellite data (Rain Satellite) and from the NDVI (a simple ratio between the red and near-infrared reflectance bands obtained from the National Oceanic and Atmospheric Administration (NOAA) polar-orbiting satellite). The NDVI correlates well with percent vegetation cover and biomass and thus the interannual fluctuations of the desert boundary, as assessed from NDVI, generally mimics that of rainfall. This work by Sharon Nicholson and coworkers at Florida State University shows considerable agreement between estimates based on rainfall and those based on NDVI and demonstrates that there is no “march” of the desert over West Africa. Plotted from data in Nicholson SE, Tucker CJ, and Ba MB (1998) Desertification, drought, and surface vegetation: An example from the West African Sahel. *Bulletin of the American Meteorological Society* 79: 815–829.

Environmental/Ecological Characteristics

Drylands occur on all continents (Figure 1). Annual precipitation is quite low, often consisting of high-intensity events that occur over short periods of time. Rainfall is also highly variable throughout the year. Most, if not all, of the annual precipitation is lost from the system via evapotranspiration (evaporated from the soil or transpired by plants), rather than via drainage to ground water or surface runoff. This is due to the high evaporative demand of the atmosphere resulting from high air temperatures, low humidity, and abundant solar radiation, that is, the potential for evapotranspiration is high. It is estimated that only 8% of the world’s renewable freshwater supply is available to drylands, which, on a *per capita* basis, is 30% less than the minimum needed for human well-being and sustainable development (Safriel *et al.*, 2005).

Quantitatively, drylands are determined by the ratio of mean annual precipitation (P) to mean annual potential evapotranspiration, which is known as the index of aridity (IA). If the IA of a region is less than 0.65, it is considered a dryland. As shown in Figure 1, drylands are classified into four types: hyperarid (IA < 0.05; examples include the Atacama, Arabian, and Sahara deserts), arid (0.05–0.20), semiarid (0.20–0.50), and dry subhumid (0.50–0.65).

The greatest concentrations of drylands are in Asia and Africa, which combined account for almost 60% of all drylands. The remaining drylands, especially when expressed on a global basis, appear relatively small (e.g., 3% in Europe and 10% in South America). However, these numbers can be deceptive: in Australia, drylands represent only 15% of the world’s total but cover nearly 90% of the land surface area of the continent.

Drylands are classified as rangelands, croplands, or urban (Figure 5). Drylands tend to have low amounts of soil organic

matter and low soil fertility. In spite of this, and the xeric nature of drylands, more than 44% of all cultivated land in the world is found within drylands (EMG, 2011). Most of the cropping systems are concentrated on the more mesic range of the gradient (in dry subhumid regions). Another notable feature is that endemic dryland plant species constitute 30% of all plants cultivated in the world (Figure 6).

Social–Economic Characteristics

Drylands are home to more than 2 billion people, or approximately a third of the total human population. Approximately 2% live in the hyperarid regions, 4% in arid, 14% in semiarid, and 15% in dry subhumid (Figure 2). Importantly, 90% of these 2 billion people live in developing countries, including 40% of the human populations of both Africa and Asia. The latter statistic is significant in that the UN World Population Prospects (2010 Revision) estimates that there will be an increase of approximately 2.3 billion in the global population by 2050, with the majority of growth attributable to “high-fertility countries” located in Africa and Asia.

Although urban systems constitute only a tiny fraction of drylands (Figure 5), they contain nearly 45% of its total population. In fact, eight of the world’s 20 megacities are located in dryland regions, for example, Cairo, Mexico City, and New Delhi. However, the remaining 1 billion people live in rural areas and thus rely directly on the land for their livelihoods. Their fate is ultimately dependent on the availability of ecosystem goods and services via rainfed or irrigated farming, harvesting native plant products, hunting, and pastoralism. Potential climate changes, limited resources, and increasing

Figure 4 Vastly different perceptions by state-holders arising from concerns over erosion gullies, illustrating how land degradation is a concept that resides in the “eye of the beholder.”

Figure 5 Land use in drylands. Reproduced with permission from United Nations Environmental Programme (UNEP) (ed.) (1997) United Nations Environmental Programme. population size increases the pressure on limited dryland resources, which can in turn lead to rapid land degradation threatening people's livelihoods.

As compared to more mesic systems, the distribution of these rural populations tend to be sparse and more mobile,

and there is a scarcity of human capital (e.g., labor). They are also apt to be physically isolated, that is, (1) located far from markets (and hence higher transaction costs) and (2) bureaucratic decisions are made by distant policymakers. As a result, dryland populations tend to lag behind populations in

Figure 6 Quinoa (*Chenopodium quinoa*) field in the Salar de Uyuni region of southern Bolivia. Quinoa has long been a staple in the diets of indigenous people of the Altiplano in the central Andes. This endemic plant played an important role in pre-Columbian Andean civilizations because of its very high protein content. Demand for quinoa in organic stores of North America and Europe in recent decades has resulted in the rapid expansion of the cultivation of this plant throughout the Altiplano. Although an economic boom, this has resulted in various forms of land degradation (due to overcultivation, the introduction of tractors, etc.; see [Figure 2\(a\)](#)) and has impacted the livelihoods of local populations in many ways (e.g., changes in diet, community structure). Ironically, the high foreign demand for quinoa means it is now less accessible for Bolivians because prices have been pushed-up.

other parts of the world with regard to many economic and health indices, such as having higher infant mortality rates, severe shortages of potable water, and lower *per capita* income (Reynolds *et al.*, 2007a,b).

Combating Desertification

Formation of the United Nations Convention to Combat Desertification (UNCCD)

Despite the work of the 1977 UNC PACD, as well as numerous other international efforts, by 1991 it was concluded that the PACD was not working and the problem of land degradation in the world was actually intensifying, rather than abating. As a result, desertification remained a major issue for the UN when they convened for the Earth Summit in Rio de Janeiro 15 years later.

At the 1992 Rio Summit, the loss of biodiversity, climate change, and desertification were singled-out as the greatest threats to humankind and sustainable development. For each, legally-binding international agreements were forged, known respectively as the Convention on Biological Diversity, the United Nations Framework Convention on Climate Change, and the UNCCD. The UNCCD (established in 1994) deals with land degradation in arid, semiarid, and dry subhumid areas of the globe, collectively known as drylands, where some of the most vulnerable ecosystems and peoples live. In fact, the *Millennium Ecosystem Assessment* (2005) concluded that “desertification is potentially the most threatening ecosystem change impacting livelihoods of the poor.”

Defining Land Degradation and Desertification

The UNCCD (1994) formally defined desertification as the “... reduction or loss of the biological and economic productivity

and complexity of terrestrial ecosystems, including soils, vegetation, other biota, and the ecological, biogeochemical and hydrological processes that operate therein... resulting from various factors including climatic variations and human activities.” Land degradation was defined as a “reduction or loss, in arid, semiarid, and dry subhumid areas, of the biological or economic productivity and complexity of rainfed cropland, irrigated cropland, or range, pasture, forest, and woodlands resulting from land uses or from a process or combination of processes, including processes arising from human activities and habitation patterns, such as: (1) soil erosion caused by wind and/or water; (2) deterioration of the physical, chemical, and biological or economic properties of soil; and (3) long-term loss of natural vegetation.” Although hundreds of definitions for desertification and land degradation have been proposed (review in Reynolds and Stafford Smith, 2002), we believe the UNCCD’s definition to be most straightforward and unambiguous.

Combating Desertification

As its title suggests (i.e., “to combat desertification”), the Convention adopted a proactive approach. What are the essential elements involved in “combating” desertification? The UNCCD adopted the following definition: “combating desertification includes activities that are part of the integrated development of land ... for sustainable development. These are activities specifically aimed at: (1) prevention and/or reduction of land degradation; (2) rehabilitation of partly degraded land; and (3) reclamation of desertified land.”

Although there are language and contextual differences, many of the goals and objectives of the UNCCD are not unlike those contained in the 1977 PACD. Hence, it is crucial to understand why the PACD failed. Three major reasons are

Table 1 Desertification involves ecological, meteorological, and human dimensions. These do not operate in isolation from each other but, rather, are closely coupled via feedbacks, synergies and interactions. Some key questions usually associated with each dimension are given here

<i>Dimension</i>	<i>Key questions (examples)</i>
Meteorological	Will changes in surface energy and water balance caused by changes in land cover significantly affect vegetation? Can changes in near surface climate caused by land degradation be translated into a recognizable contribution to global-scale changes, that is, a desertification “warming signal?” Do bio-geophysical feedback-based climate models contain sufficient mechanism to accurately predict droughts? What is the relationship between the loss of vegetation, albedo, surface roughness, and drought? Will global climate change exacerbate the high natural variability of precipitation and temperature in drylands?
Ecological	Are short-term ecosystem dynamics (e.g., decreases in plant cover) indicative of desertification? Do long-term changes in dryland ecosystems alter the resource base of the entire system such that it moves beyond a threshold whereby degradation accelerates and becomes irreversible? Do multiple thresholds exist? How do the key physical drivers influence other factors such as animal disease carriers, for example, how do temperature and drought affect insect behavior? When is animal production a function of rainfall (plant production) and when is it decoupled? If global climate change further exacerbates the already high natural variability of precipitation in dryland ecosystems, will this lead to permanent degradation of their productive potential, particularly since there is a lack of “buffering” by large reserves of organic matter in the soils or in woody vegetation? Can “early warning” functional indices (based on soils, vegetation, biota, and ecological, biogeochemical, and hydrological processes) be developed to indicate major physical restructuring of a system symptomatic of land degradation? What impact do exotic species have on land degradation processes? What is the relationship of bush encroachment to desertification processes?
Human	How do human populations in the various natural, seminatural, and intensively-managed dryland ecosystems of the globe, affect those ecosystem goods and services considered vital to the sustainability of human populations? What are the key socioeconomic drivers of land use that lead to desertification? For example, is there a relationship between how land is used (accountability) and ownership (which tends to be low in poor countries and high in rich ones)? Are regional and national programs to combat desertification based on economic integration and sustainability of local people who are most directly affected? How can local people be integrated into the decision-making process? Is the “stake-holder” concept a feasible one at all scales of interest? Is it possible to reconcile the different viewpoints of different stakeholders in relation to desertification issues? What are the respective roles of government, local communities, and land users in maintaining sustainability of drylands? Do ecologically-sound land-use practices lie at the level of recognizing the rights and environmental knowledge of local communities? What resources are needed to accomplish this? What is the response of human activities to different stages of land degradation? Are there adaptive adjustments? What is the role of technology in providing new opportunities for ecological sustainability in drylands of the globe?

most often cited: (1) many processes and issues leading to land degradation, for example, overcultivation of the land, deforestation, overgrazing by livestock, and poverty, have their roots in socioeconomic and political realms, and thus are not amenable to technical or science “solutions” as proposed in the PACD; (2) local populations were not included in drawing up solutions; and (3) there was a failure to integrate the PACD into other existing development programs. These problems reflect the failure to recognize the simultaneous importance of meteorological, ecological, and human dimensions of land degradation (Table 1).

Recognizing these shortcomings, the Earth Summit supported a new, integrated approach to the desertification problem, emphasizing programs and strategies to promote sustainable development at the community level. Consequently, the UNCCD places considerable emphasis on the social dimensions of the problem and the role of local peoples and nongovernmental organizations in solving local problems. There is a conspicuous emphasis on the human dimensions (a “grass-root” effort). There is now a clear

recognition that regardless of emphasis, dryland degradation – given its ecological, meteorological, and human dimensions (Table 1) – requires contributions from a multitude of disciplines to understand and identify useful resolutions (Reynolds *et al.*, 2007a).

10-Year Strategy

In 2007, a new 10-year strategy of the UNCCD (2008–2018) was implemented with the goal “... to forge a global partnership to reverse and prevent desertification/land degradation and to mitigate the effects of drought in affected areas in order to support poverty reduction and environmental sustainability.” The new strategy is composed of three general strategic objectives. A list of these objectives and their anticipated benefits are given in Table 2.

At the 2011 UNCCD conference in the Republic of Korea, UN Secretary-General Ban Ki-moon reaffirmed the importance of global desertification to the world community: “If we

Table 2 As the UNCCD entered its second decade, it adopted a new 10-year strategic plan (2008–2018) to enhance its implementation (EMG, 2011)

<i>Strategic objectives</i>	<i>Expected benefits</i>
To improve the living conditions of affected populations	● People living in areas affected by desertification/land degradation and drought to have an improved and more diversified livelihood base and to benefit from income generated from sustainable land management. ● Affected populations' socioeconomic and environmental vulnerability to climate change, climate variability, and drought is reduced.
To improve the condition of affected ecosystems	● Land productivity and other ecosystem goods and services in affected areas are enhanced in a sustainable manner contributing to improved livelihoods. ● The vulnerability of affected ecosystems to climate change, climate variability, and drought is reduced.
To generate global benefits through effective implementation of the UNCCD	● Sustainable land management and combating desertification/land degradation contribute to the conservation and sustainable use of biodiversity and the mitigation of climate change.
To mobilize resources to support implementation of the Convention through building effective partnerships between national and international actors	● Increased financial, technical, and technological resources are made available to affected developing country Parties, and where appropriate Central and Eastern European countries, to implement the Convention. ● Enabling policy environments are improved for UNCCD implementation at all levels.

protect, restore and manage land and soils we can tackle many challenges simultaneously, such as poverty, food and energy insecurity, biodiversity loss, climate change, forced migration, and geopolitical instability.”

Drivers of Desertification

Proximal and Underlying Factors

Desertification is driven by factors that vary from region to region. Geist and Lambin (2004) conducted an analysis of over 130 existing case studies (from throughout the world) in an attempt to elucidate patterns. They identified four major categories of proximal causal agents (i.e., drivers) (Figure 7): (1) increased aridity; (2) agricultural impacts, including livestock production and crop production; (3) wood extraction and other economic plant removal; and (4) infrastructure extension, which could be separated into irrigation, roads, settlements, and extractive industry (e.g., mining, oil, and gas). Only 10% of the case studies were driven by a single cause (with approximately 5% due to increased aridity and 5% to agricultural impacts). Approximately 30% of the case studies were attributable to a combination of two causes (primarily increased aridity and agricultural impacts), whereas the remaining cases were combinations of three or all four proximal causal factors.

Certain drivers are more or less important in a given region. The drivers evolve from underlying forces associated with specific socioeconomic and biophysical factors characteristic of a particular region. For example, Geist and Lambin found that two underlying drivers, climate and technological factors (either new technologies or deficiencies in technology) were the key drivers of desertification in the majority (54%) of case studies in southern Europe. In Africa, they found

that climate, alone or acting in concert with population demography, was a key driver in the 38% of the case studies whereas in the USA, 50% of the case studies were attributable to a combination of climate and technology drivers or these two factors interacting with economic ones. Desertification processes in Asia, Latin America, and Australia could only be attributed to more complex interactions among four or more underlying forces.

Climate Change

One of the conclusions of the Fourth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) is that many dryland areas of the globe will suffer decreases in water resources as a result of climate change. Both Africa and Asia are expected to experience major changes, for example, increasing air temperature and changes in precipitation (total amount and season distribution). Under a range of climate change scenarios, the IPCC posits that arid and semiarid land in Africa will increase by 5–8% by 2080; overall, lower precipitation will lead to lower agricultural production in many African countries. In Asia, especially in the central, south, east, and southeast, freshwater availability is projected to decrease in the next 40 years.

Global warming-induced droughts will likely exacerbate land degradation. People will likely have to endure greater and more frequent weather extremes (droughts, flooding). However, it is important to note that humans have the capacity to adapt. For example, in the Sahel of West Africa there was a decline in average rainfall of more than 30% between the 1960s and the 1990s, yet a rapidly growing human population ultimately survived, demonstrating the capacity to adapt to climatic uncertainty in the future (EMG, 2011).

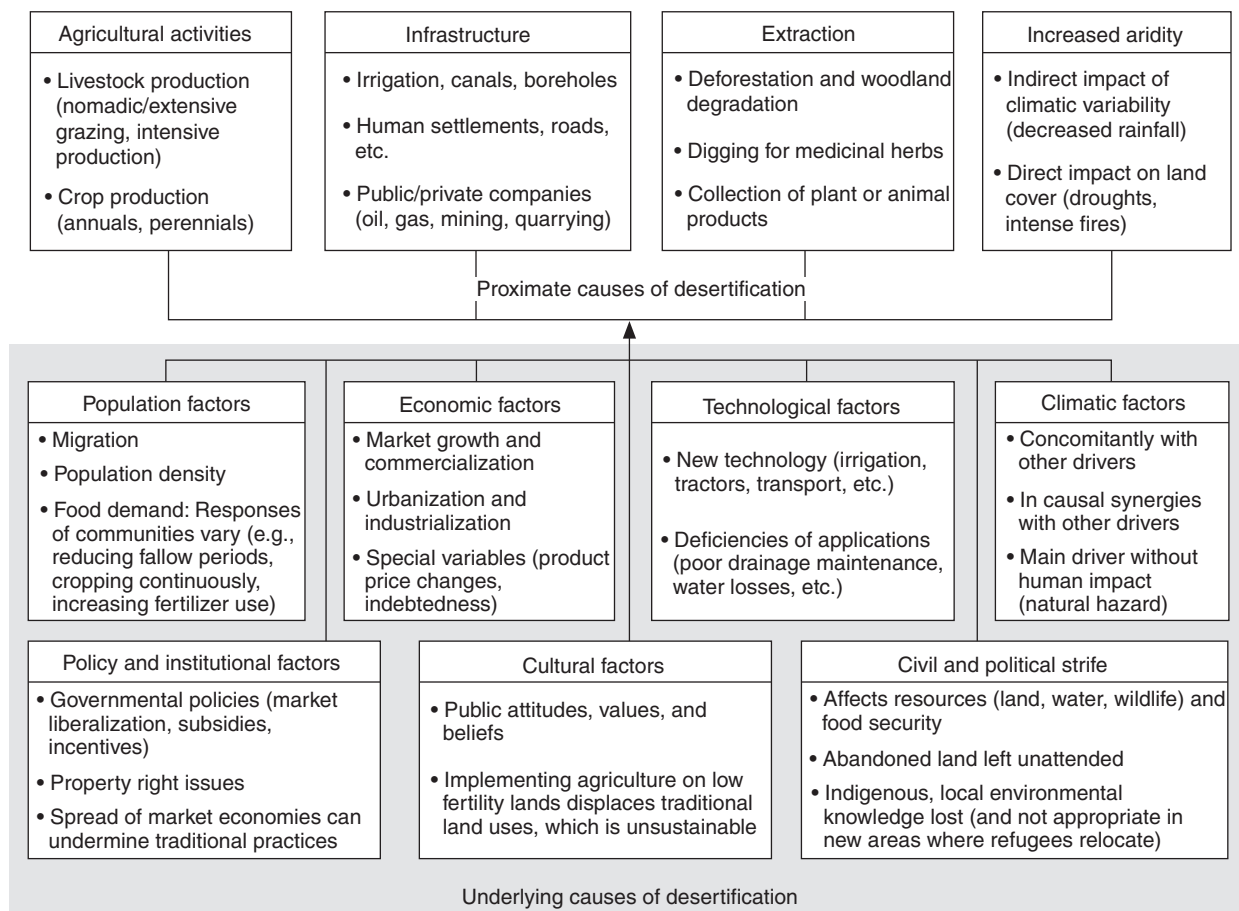

Figure 7 In a global survey Geist and Lambin found repeating causal patterns for drivers of land degradation, which resolved into four major proximate causes explained by six major underlying drivers. Modified from Geist HJ and Lambin EF (2004) Dynamic causal patterns of desertification. *Bioscience* 54: 817–829, with permission from University of California press.

Drylands may also play an important role in mitigation of climate change via the potential for sequestering of carbon in soils. Whereas on a per unit area basis drylands may have a low sequestration rate, their large expanse (~40% of the land area of the globe, **Figure 1**) makes them very important.

Dimensions of Desertification

As alluded to above, we view desertification in terms of its (1) meteorological dimensions, (2) ecological dimensions, and (3) human dimensions (**Table 1**). Each of these is by itself quite complex and difficult to predict. Importantly, the three are highly interdependent. A failure to recognize the simultaneous role of – and feedbacks between – these three dimensions has led to many of the controversies and misconceptions alluded to above. In this article, we explore the concept of desertification based on these critical dimensions.

Ecological Dimensions

Short- versus Long-Term Ecosystem Dynamics

Nearly all drylands are characterized by extreme year-to-year precipitation fluctuations. Hence, it is often difficult to

distinguish between short-term variability and long-term changes in ecosystem appearance, as well as between temporary and permanent changes. Short-term variability in precipitation tends to affect the range and frequency of resource pulses, whereas long-term change alters the resource base: that is, the entire system moves beyond some threshold. Once this threshold has been crossed, it is unlikely that the system can be returned to its predisturbed state, without expensive and often extensive remediation efforts. All of this depends on the interactions of numerous climatic, edaphic, and biological factors in combination with the economic feasibility of rehabilitation.

We have stressed the inherent difficulties in teasing out underlying causal factors that give rise to short- versus long-term ecosystem dynamics in drylands (e.g., **Figure 3**). A case study from the Serengeti in Tanzania is an excellent illustration of this. In the 1970s, there was much concern that the Serengeti was degrading and turning into a “desert.” The large bush and acacia forests that characterized the Serengeti were declining at an alarming rate. Elephants – who fed on these trees – were largely considered responsible and many believed that a culling program was the only way to save these “pristine” woodlands. In fact, these woodlands were not pristine but instead a relatively recent feature of the Serengeti

decreased efficiency of nutrient cycling, and increased nutrient losses from the system. Both native perennial plants (cover and biomass) and many associated microbial and animal populations are reduced, whereas exotic species increase in dominance. All of this results in a decrease in the biological and, hence, economic potential of the land.

“Greening” of Drylands

In recent years, numerous studies have reported a “greening-up” of drylands over large regions of the globe. These data are akin to those presented in [Figure 3](#) relating normalized difference vegetation index (NDVI) to precipitation. For example, using data from 1983–2003, [Helldén and Tottrup \(2008\)](#) found a strong greening trend in the Sahel (from west to east), moderate greening in the Mediterranean and East Asia, but insignificant greening in South Africa and South America. They suggest that the very strong greening found in the Sahel is potentially a return to pre-Sahelian-drought rainfall conditions, whereas climatic changes may be responsible for enhanced plant growth in the Mediterranean and East Asia. These trends appear at odds with the UNCCD view that desertification is increasing worldwide in response to climate change, population growth, unsustainable land-use practices, and urbanization. However, due to numerous time and spatial scale issues, technical concerns, and other unknowns, Helldén and Tottrup conclude that “at the moment there is no clear understanding of this dryland “greening,” although it is recognized that an explanation must include both biophysical as well as human factors.”

Meteorological Dimensions

Substantial improvements have been made in our understanding of the causes of interannual variability in dryland climates, including the natural causes of droughts. For example, it is accepted that variations in annual precipitation levels are related to natural variations within the global-scale climate systems. However, great uncertainties remain, and the relationship between desertification and climate resembles the proverbial “chicken and egg” problem. To what extent does climate induce desertification? How do changes in land surface properties due to land degradation, in turn, affect climate? Since the two processes often work together, it is virtually impossible to separate the impact of drought from that of desertification.

Drylands are particularly vulnerable to climate variability, of which precipitation is the most important component. For example, a slight shift in seasonal precipitation and/or frequency of extreme rain events could potentially lead to the overexploitation of the meager resources of drylands and contribute to the further degradation of the resource base on which human populations are so dependent. Preliminary studies with general circulation models (GCMs) in the 1980s projected that a doubling of atmospheric carbon dioxide (due to the rapidly expanding human population and associated activities) would result in lower precipitation, as well as shifts in the timing and frequency of rains, in the interior of large continents. Recent GCM studies also predict increases in rainfall intensity and longer dry periods in many dryland regions

of the globe. In the long run, global climate change may further exacerbate the already high natural variability of drylands, leading to permanent degradation of their productive potentials, particularly since there is a lack of “buffering” by large reserves of organic matter in the soils or in woody vegetation.

The array of impacts of climate on land and the implications of degraded land surface for the climate system are varied and complex. Human activities impact surface characteristics (and, hence, its albedo) and the atmospheric composition of dryland regions, including the breakdown of soil structure, reductions in soil moisture, increased surface runoff, changes in species composition and cover, increase dust in the atmosphere, and increases in aerosol and trace gas emissions from burning. In response to such human impacts, dryland climate is greatly influenced mainly via changes in energy balance. Changes in albedo affect the amount of solar radiation absorbed by the surface and changes in soil moisture levels affect the portion of energy used in evaporation and transpiration processes. Changes in surface roughness influence wind speeds and turbulence, which have a bearing on evapotranspiration. Finally, changes in atmospheric composition may affect atmospheric temperature profiles, and thus influence capacity to generate precipitation over land.

Human Dimensions

Rapidly changing social and economic conditions – along with the potential for climate change – pose serious challenges to many dryland regions of the world. Globally, there are differences in socioeconomic factors (e.g., human population growth rates) and biogeography (e.g., natural vegetation), which play a large role in the type of major human activities in any given area. Moreover, there are differences in how human interference is affecting biodiversity and ecosystem functioning in poor and richer countries. Taking these differences into account, there are roughly six major classes of human interference in drylands:

1. the loss of habitat;
2. the fragmentation of crucial habitat;
3. overexploitation (mainly overgrazing by domestic animals);
4. the spread of exotic organisms (aliens);
5. air, soil, and water pollution; and
6. climate change.

Although it is somewhat difficult to generalize about the vulnerability of terrestrial ecosystems, some problems virtually exist everywhere (e.g., habitat loss, habitat fragmentation, and the direct and indirect effects of exotic species), whereas pollution and climate change tend to be more significant threats in richer, temperate zone nations. Key ecosystem “goods and services” (e.g., food, construction materials, water purification, flood control, climate regulations, soil maintenance, carbon sequestration, nutrient recycling, wildlife habitat, erosion control, tourism/recreation, etc.) are being seriously affected ([Table 3](#); see Ecosystem Services).

Given that all three of the developing regions of the world – Africa, Asia, and Latin America – have similar percentages of land degradation, and the highest levels of population growth, desertification is a growing problem with major ecological,

Table 3 Four broad categories of ecosystem services used by the Millennium Ecosystem Assessment (MEA), including a general assessment of their economic value and application to drylands

<i>Service</i>	<i>Brief explanation</i>	<i>Examples</i>	<i>Economic value</i>	<i>Application to desertification</i>
Provisioning (=“goods”)	Material items for direct or near-direct human use. Globally, often at the expense of the other types of services, there has been a trend to increase production of most provisioning services, largely due to the expansion and intensification of agriculture.	Crops, forage, livestock, wild-caught fish or animals, freshwater, timber, fuel, fiber.	Provisioning services are relatively easy to quantify and value, since formal or informal markets often exist, and where they do not, substitute values can be estimated.	Desertification is often a direct consequence of overuse of provisioning services, driven by complex external and internal factors such as population pressures and poverty. Examples of declining provisioning services in drylands include wild plant and animal products, fuelwood, genetic resources, clean air, and freshwater.
Regulating	Keep the flow of other ecosystem services within a desired range, and prevent ecosystem “disservices” such as natural disasters from getting out of hand. The MEA suggests that globally 70% of regulating services have been degraded. At a global scale, climate change can be seen as a breakdown of climate regulating services.	Pollination, climate regulation, flood attenuation, air and water quality maintenance, pest regulation.	Drylands are inherently variable so valuing these services is difficult (the value of regulating services is often delivered via other services). Nevertheless, an increase in certainty and a decrease in risk have economic value. The breakdown of regulating services can have dire social and environmental consequences.	Vegetation cover buffers both the hydrological and production systems. The weakening of regulating services can be slow and continuous, or irregular and only apparent during extreme events. For instance, catastrophic floods may be a combination of reduced infiltration, reduced slowing of overland flow due to a combination of soil compacting and the loss of ground cover coupled with an intense storm event.
Cultural	Cultural services make the world a place in which people want to live. The MEA suggests there has been a rapid decline in many cultural services over the past century.	Recreation, esthetic, artistic appreciation, educational, scientific benefits, spiritual inspiration, sense of place.	People of all cultures value nature. Many of these services are easily quantified and valued, because well-established markets exist, such as for ecotourism. Others require more indirect approaches, such as hedonistic pricing, for example, the increase in value of a property when it has a nice view.	Empirical evidence suggests cultural services are readily traded for provisioning services in times of need, or simply because their economic value is not appreciated. For example, some dryland ranchers use excessive stocking rates to maximize short-term profit with the knowledge that it will lead to destructive feedbacks (erosion, loss of plant cover) to the very land they value.
Supporting	Underlying ecosystem processes that allow provisioning, regulating and cultural services to be provided. Often constitute the “slow variables.”	Net primary production, habitat for biodiversity, soil formation and nutrients cycling.	Always delivered via provisioning, regulating and cultural services, and should be valued through those other services to avoid double counting.	In desertification it is typically the reduction of supporting services that ultimately leads to the persistent decrease in the ability of the system to provide provisioning and regulatory services.

economic, and social implications. However, to understand the human dimensions of desertification, it is important to compare and contrast different regions of the world to each other, seeking out generalities, particularly in richer versus poorer countries. As new economic policies are adopted, many pastoral and dryland farmers are marginalized and must move to urban areas; socioeconomic conditions are rapidly changing, for example, the rise of tourism, intensification of high-tech agriculture, and the shifting of populations to urban environments. Often, such changes result in the abandonment of land for traditional agriculture and the rise in demand for water for urban expansion, tourism, and irrigation, resulting in increased land- and resource-use conflicts.

The human dimensions of desertification represent some of the most complicated and perplexing issues in identifying the causes of and solutions to land degradation. For example, in large areas of Africa, civil strife and government policies are key factors influencing resources (land, water, and wildlife), land degradation, and food security. Civil strife displaces people, often to other marginal lands and in great numbers; their abandoned land is left unattended, indigenous management systems are lost, and they are forced to use methods of ranching and farming that are often not appropriate in these new areas. In some countries, government policies have encouraged planned human settlements in the wetter margins of arid and semiarid lands or nearer to water supplies. This has led to land-use conflicts between agriculture, livestock, wildlife, and human settlements, as a result of the intrusion of agriculture into lands traditionally used for domestic stock.

Ecosystem Services

Reduction in the provision of ecosystem services as a result of water scarcity, overintensive use of services, and climate change is a much greater threat in drylands than in nondryland systems (Table 3). As noted, a key feature of most dryland areas is that there is a very tight, direct coupling between human livelihoods and use of natural resources (for instance collecting firewood, obtaining water from wells, hunting game, and raising livestock). Hence, the protection of the supporting services is critical in drylands because they underpin all the other services, and degradation is expensive and difficult (sometimes effectively impossible) to reverse (Table 3).

In the section Combating Desertification, the author suggests the UNCCD's definition of land degradation and desertification ("the reduction or loss of the biological and economic productivity and complexity of terrestrial ecosystems ... resulting from various factors including climatic variations and human activities") to be the most straightforward and unambiguous one available. The *Millennium Ecosystem Assessment* (2005) expressed this definition in terms of the balance between the demand and supply of ecosystem services that support the well-being of humans. Since human needs change over time, the viability of achieving and maintaining sustainable livelihoods depends on a suite of ecosystem services, rather than any single one (see Table 3).

This is the objective of sustainable land management, which is defined as "the use of land resources, including soils,

water, animals and plants, for the production of goods to meet changing human needs, while simultaneously ensuring the long-term productive potential of these resources and the maintenance of their environmental functions" (Liniger *et al.*, 2011). Nevertheless, not all ecosystem services are equally vulnerable to degradation and have differing importance. Within limits, trade-offs can be made between services of different types without incurring degradation but the non-linear responses of ecosystem services to human appropriation must be considered as critical thresholds exist and, in some cases, once surpassed trade-offs cannot be safely made. For example, poorly managed cropland or the conversion of rangeland to cropland may affect multiple services (especially provisioning, regulating, and supporting) resulting in increased pressure on the remaining natural resources that have impacts beyond the local scale. Often, the expensive use of external inputs such as irrigation and fertilization may ensure a positive balance of services locally, but in the long term can lead to desertification through processes such as water-logging and salinization of the soil.

The Dryland Development Paradigm

With regard to addressing the causes and consequences of desertification, we can summarize the main points in this article as follows:

1. ecological, meteorological, and human (social-economic) variables interact to form coupled human (H)-environmental (E) systems;
2. change in these coupled H-E systems is omnipresent but is manifested in different ways, for example, slowly evolving (or chronic) and abrupt;
3. H-E systems are not in equilibrium, often exhibiting multiple ecological and social states;
4. cross-scale interactions between humans and the environment are scale-dependent (see Figure 6); and
5. local environmental knowledge (LEK) can play an important role in understanding both short- and long-term processes.

Based on the three dimensions of desertification (Table 1) and the aforementioned summary points, Reynolds *et al.* (2007a) proposed the Dryland Development Paradigm (hereinafter, the 'DDP'), which is a new synthetic framework for global desertification. The DDP consists of five principles (P1-P5, Table 4). This conceptual model has practical implications for an effective approach for understanding H-E systems and formulating models useful for decision-making. A conceptual model is shown in Figure 9.

As noted under dryland syndrome (see The Dryland Syndrome), there is a close dependency of human livelihoods (H) on the environment (E) in drylands. These dependencies are dynamic, always changing (P1, Table 4). The critical linkages between these subsystems are created by (1) human activities and decision-making on the one hand (H→E) and (2) environmental controls and feedbacks pertaining to the flow of ecosystem services on the other (E→H). As a result, ecosystem goods and services of importance to local

Table 4 Five principles of the DDP, for coupled H–E systems, their significance and implications for research, management and policy

<i>Principle</i>	<i>Why important in drylands</i>	<i>Key implications for research, management, and policy</i>
P1: H–E systems are coupled, dynamic, and coadapting, so that their structure, function, and interrelationships change over time.	The close dependency of most drylands livelihoods on the environment imposes a greater cost if the coupling becomes dysfunctional; variability caused by biophysical factors as well as markets and policy processes, which are generally beyond local control, means that tracking the evolving changes and their functionality is relatively harder and more important in drylands.	ki-1: Understanding dryland desertification and development issues always requires the simultaneous consideration of both human and ecological drivers, and the recognition that there is no static equilibrium “to aim for.”
P2: A limited suite of “slow” variables are critical determinants of H–E system dynamics.	Identifying and monitoring the key slow H and E variables is particularly important in drylands because high variability in “fast” variables masks fundamental change indicated by slow variables.	ki-2: A limited suite of critical processes and variables at any scale makes a complex problem tractable.
P3: Thresholds in key slow variables define different states of H–E systems, often with different controlling processes; thresholds may change over time.	Thresholds particularly matter in drylands because the capacity to invest in recovering from the impacts of crossing undesirable thresholds is usually lower per unit (area of land, person, etc.); and, where outside agencies must be called on, the transaction costs of doing so to distant policy centers are usually higher.	ki-3: The costs of intervention rise nonlinearly with increasing land degradation or the degree of socioeconomic dysfunction; yet high variability means great uncertainty in detecting thresholds, implying that managers should invoke the precautionary principle.
P4: Coupled H–E systems are hierarchical, nested, and networked across multiple scales.	Drylands are often more distant from economic and policy centers, with weak linkages; additionally, regions with sparse populations may have qualitatively different hierarchical relationships between levels.	ki-4: H–E systems must be managed at the appropriate scale; cross-scale linkages are important in this, but are often remote and weak in drylands, requiring special institutional attention.
P5: The maintenance of a body of up-to-date LEK is key to functional coadaptation of H–E systems.	Support for LEK is critical in drylands because experiential learning is slower where monitoring feedback is harder to obtain (owing to more variable systems, larger management units, in sparsely populated areas) and, secondarily, where there is relatively less research.	ki-5: The development of appropriate hybrid scientific and LEK must be accelerated both for local management and regional policy.

Source: Reproduced from Reynolds JF, Stafford Smith DM, Lambin EF, *et al.* (2007a) Global desertification: Building a science for dryland development. *Science* 316: 847–851.

populations are changing and evolving over time. This close dependency of livelihoods on the environment may impose a high cost if the H–E linkages become unbalanced or dysfunctional (P1). Often this is due to variability caused by biophysical factors as well as markets and policy processes, which are generally beyond local control, means that tracking any changes that are occurring (which is always happening) and their overall importance to the stability of the H–E balance is crucial but very difficult.

The DDP emphasizes the importance of “slow” or controlling variables in both H and E domains (P2). For example, terrestrial primary production is dependent on both soil moisture and nutrients; however, nutrients in the soil change very slowly over time (hence, is a “slow” variable), whereas the residence time of soil water changes very rapidly (a “fast” variable). “Slow” variables are important, because they actually control changes of state, whereas “fast” variables usually reflect unimportant variability within states. For example, at any

given time, the degree of soil fertility would be more important to a management decision than soil water content (the latter of which will change within hours).

As discussed, thresholds matter in drylands. However, the DDP posits that only thresholds of interest should be the “slow” variables. If a threshold is crossed, it can lead to major imbalances in the entire system. Furthermore, the capacity of H–E systems to recover from the impacts of crossing undesirable thresholds is often slow and if distant policy centers must be called on for assistance, the transaction costs of doing so are usually high (P3, Table 4).

The principles of the DDP introduced thus far – that is, “slow” and “fast” variables, thresholds and constant changes in the interactions, and thus balance of H–E interactions – all depend on the scale of interest (P4, Table 4), of which there are numerous ones. For example, the slow variables of interest regarding the welfare of a single household, an ejido (in Latin America, this is communal land shared by all people of a

Figure 9 Schematic depicting interactions between human (H) and environmental (E) components of the land system. P1–P5 refer to DDP principles in Table 2. These systems coevolve as balanced networks of feedbacks and interactions between H–E components in spite of constantly changing external drivers. Decision-making ($H \rightarrow E$) and ecosystem services ($E \rightarrow H$, e.g., grazing land and clean air) are key linkages between components (moderated by an effective system of LSK, P5). Many studies have tended to focus on each subsystem (i.e., $H \rightarrow H$ and $E \rightarrow E$) at the expense of the linkages between them. Reproduced from Verstraete MM, Scholes RJ, and Stafford Smith M (2009) Climate and desertification: Looking at an old problem through new lenses. *Frontiers in Ecology and the Environment* 7: 421–428, with permission from ESA.

community), or a nation may be quite different. In managing H–E systems, such cross-scale linkages are important in decision-making, but in drylands they are often remote and weak, requiring special institutional attention and monitoring support (see The Dryland Syndrome).

Lastly, the loop in Figure 9 implies that links between the H and E subsystems are mediated in practice by human mental models and local and scientific knowledge (LSK) (P5, Table 4). Differing management and policy decisions are often dependent on LSK. “Local knowledge” *per se* is not always very local: It may be the knowledge of distant policymakers about how their institutions operate as much as local farmers’ understanding of the effects of different levels of grazing.

Conclusions

Desertification (land degradation in drylands) is the loss of biological and economic productivity, and biodiversity in arid and semiarid croplands, pastures, rangelands, and subhumid woodlands of the world. It is due mainly to unsustainable human activities, such as overcultivation, overgrazing, deforestation, and poor irrigation practices and is often triggered or exacerbated by climate variability, mainly drought. A new integrated assessment paradigm, the DDP, has been proposed as a tool to aid in tackling the complexity of this phenomenon. The DDP, which is based on the simultaneous roles and complex feedbacks among the meteorological, ecological, and human dimensions of this problem, provides a roadmap (not

a recipe) for thinking about drylands management issues. Historically, the failure to recognize and include the interdependencies of these three dimensions has slowed progress by the UNCCD in tackling the enormous problem of dryland degradation, although recent developments are encouraging. International researchers – representing a wide range of disciplines such as ecology, atmospheric science, social sciences, policy, and integrated assessment – must work together to successfully address this pressing global problem.

Glossary

Disturbance Relatively discrete event in time that disrupts ecosystem, community, or population structure and changes resources, substrate availability, or the physical environment.

Disturbance regime The collective spatial, temporal, physical, and ecological characteristics of a disturbance process operating in an area.

Resilience Measure of a system's ability to recover to its original state when subjected to disturbance.

Resistance A measure of system's ability to remain unchanged when subjected to a disturbance.

Disturbance Ecology

Ecological communities are subjected to sharp environmental perturbations such as the passage of a fire, a storm wave, an avalanche, or a large animal, that suddenly reduce standing biomass. Such events also alter ecosystem properties such as energy balance, nutrient fluxes, substrate texture, and chemistry. Generally referred to as "disturbances," these events are distinguished as a special form of environmental variability because they are relatively discrete in both time and space and cause unusual mortality or tissue loss in affected populations. Disturbances promote environmental heterogeneity and free up limiting resources, such as space, light, and nutrients, thereby triggering successional processes of community recovery.

Widespread agents of disturbance in terrestrial ecosystems include fire, wind, extreme temperature, desiccation, gravity (as a force on water, ice, rocks, and soil), and organisms. With the exception of fire, one can find analogs in aquatic systems, in which the main agents are heat, solutes, currents, desiccation, waves, ice, sediments, and organisms. Disturbance agents operate by exerting mechanical force, altering physico-chemical conditions, or through biological consumption and disease. Practically, any physical mass can mechanically disturb ecosystems at some scale provided it has sufficient velocity to dislodge organisms or kill tissues. In contrast, disturbance by fire involves chemical combustion of biomass. Disturbance of terrestrial communities by prolonged inundation is largely a chemical disturbance resulting from oxygen depletion. Freshets in estuarine and marine environments are also chemical disturbances. These mechanical and physico-chemical disturbances contrast with biological disturbances such as herbivory or predation, which involve tissue removal and digestion by individual mobile consumers.

During the first half of the twentieth century, ecologists paid more attention to postdisturbance processes of species recovery and community succession than to specific disturbance mechanisms. Disturbance was generally treated as a temporary setback to communities that otherwise would tend to develop toward a relatively steady state or "climax community" whose structure and composition were determined by climate and other physical factors and were regulated by endogenous biological interactions. Recently, disturbance has been recognized as intrinsic to and ongoing in virtually all

ecological systems. Closer attention has been paid to disturbance processes and their role in promoting characteristic scales of spatial and temporal environmental heterogeneity and in regulating ecosystem processes, population dynamics, species interactions, and species diversity (Paine and Levin, 1981; Sousa, 1984; Pickett and White, 1985; Turner, 2010). Efforts to improve the understanding of disturbance mechanisms have accelerated due to concern over the effects of global environmental change on disturbance regimes and associated ecosystem dynamics.

In practice, it may not be easy to distinguish disturbances from other environmental variation. Most agents of disturbance operate over a continuum, and environmental perturbation is sudden and severe only relative to some set of reference conditions and from the perspective of the affected organisms. The mound of soil produced by a burrowing gopher is a significant disturbance to the underlying herbaceous plants and soil animals but likely to be of little consequence to a large tree, a few meters away. A windstorm that topples trees in an open savanna may have no immediate effect on small herbaceous plants located a short distance outside of the canopy. Thus, it is important to bear in mind that disturbance is a relativistic concept and it can span a very broad range of spatial and temporal scales. Not surprisingly, the term disturbance has been applied somewhat indiscriminately in ecology. The most general definition of a disturbance – any process that causes a sudden decrease in standing live biomass and frees up ecological resources (Sousa, 1984) – is perhaps the most unambiguous. Another widely used definition, provided by White and Pickett (1985, p. 7) is "any relatively discrete event in time that disrupts ecosystem, community, or population structure and changes resource, substrate availability, or the physical environment".

A disturbance differs from a stress in that the latter is a more chronic condition inhibiting the growth or normal functioning of an organism (e.g., a lack of key nutrients or physical abrasion). A disturbance is termed a catastrophe if it causes extraordinary ecological impact.

Variables commonly used to describe a single disturbance event include timing, extent, and magnitude, where magnitude encompasses both intensity (e.g., energy per area per time) and severity (biological impact). These and other stochastic variables, such as event frequency or recurrence interval

between events, have statistical properties that serve to define a disturbance regime. More broadly, a disturbance regime is the collective spatial, temporal, physical, and ecological characteristics of a disturbance process operating in an area. Predictability, which can be defined as the inverse of the variance in disturbance frequency, size, and magnitude (Christensen, 1988), is also an important consideration. In general, predictability increases as the spatio-temporal scale of analysis is expanded from local (the typical size of a disturbance event) to landscape or regional domains (the entire area over which the disturbance regime is manifested).

Because the magnitude of disturbance is defined relative to its ecological impact, it is practically tautological that disturbance regimes are dominated by events of relatively low magnitude and high frequency, whereas higher magnitude events are increasingly rare. However, the impact of a disturbance may not increase linearly with size, frequency, or duration. Romme *et al.* (1998) distinguished three classes of disturbance response: (1) threshold response, (2) scale-independent response, and (3) continuous response. Individuals and communities manifest threshold responses when there are discrete limits in their ability to resist a large disturbance (e.g., the wind speed at which a tree is uprooted). Disturbances can have their greatest ecological impact when one or more events follow close on the heels of another, preventing or disrupting normal community recovery (Paine *et al.*, 1998).

Some mechanisms of disturbance, such as earthquakes or storm waves, are exogenous to the biological communities being impacted, whereas others such as treefall or fire could be considered endogenous. In the former, there is little or no feedback between the state of the ecosystem and the likelihood of a disturbance event so that the disturbance regime depends mainly on location and environmental context. In the latter, the likelihood of a disturbance depends on the state of the ecosystem as well as location. Although the categories of endogenous and exogenous disturbances are somewhat artificial, it is useful to examine the relative strength of coupling between disturbance processes and the biota. In many cases, disturbance processes and their effects are tightly coupled to the biological properties of individual organisms and communities. This coupling may promote the formation of specific scales of ecological pattern and reinforce certain ecological and evolutionary processes (Levin, 1992).

In thinking about patterns and processes, it is also useful to distinguish spatially propagating from nonpropagating disturbances (Reiners and Driese, 2003). Disturbances such as fire and flood spread from neighboring areas, and the spatial pattern of "susceptible" areas or organisms may have a constraining effect on disturbance dynamics, thereby linking spread to previous disturbance events.

Disturbance and Biodiversity

The "intermediate disturbance hypothesis" (IDH; Connell, 1978) predicts that maximum levels of biodiversity should be observed under some intermediate disturbance frequency because few species are able to tolerate very intense disturbance regimes, and few are able to compete successfully in habitats that experience little or no disturbance. The IDH also implies

that maximum diversity should be found at some intermediate span of time since the last disturbance. The IDH has been expanded to incorporate intermediate levels of disturbance intensity and extent, and it has been tested and supported in a wide variety of ecosystems.

The best experimental examples of the IDH come from the study of sessile species competing for space or some space-associated resource. Counter-examples come largely from the study of mobile consumers (e.g., freshwater invertebrates), for which rapid immigration may override local disturbance effects. Defining "intermediate" in the context of specific organisms and choosing the scale to measure diversity are also important issues in assessing the validity of the IDH, about which there is ongoing debate. In general, the IDH applies to small-scale disturbances and to plants and sessile filter feeders. The relationship between disturbance and diversity is more complicated at larger scales and may not apply when interactions among multiple trophic levels are considered.

At spatial scales, much larger than the characteristic size of single disturbance events, disturbance regimes generate disturbance mosaics that maintain beta diversity in landscapes or regions by promoting coexistence of dispersal-limited competing species or prey species and by maintaining environmental heterogeneity and multiple serai stages (Pickett and White, 1985).

If they recur with sufficiently high frequency (e.g., on average at least once per generation), ecological disturbances can be a strong selective force operating on species' morphology, physiology, and behavior. Not surprisingly, many organisms are adapted to or depend on specific kinds of disturbances and disturbance regimes. Grime (1979) proposed that herbaceous plant life histories can be ordered along three fundamental axes: stress tolerance, competition, and disturbance. Somewhat analogously, animal species are often called *r*-strategists or *k*-strategists depending on whether they have high intrinsic rates of reproduction and tend to be favored by disturbances or whether they have lower reproductive rates but exert competitive dominance in the absence of disturbance. Because local abundance of many species is increased or maintained by disturbance, the long absence of specific kinds of disturbances (e.g., fire or floods) may have large negative impacts on biodiversity.

The life history strategies of some organisms may promote specific disturbance regimes (e.g., some fire-adapted shrub species possess canopy structure and foliar chemistry that promote fire spread). Organisms that recover quickly after a disturbance are said to be resilient to that disturbance, as opposed to those that show little response to disturbance and are considered resistant. These concepts are also applied to ecological communities, and the relationship between community diversity and community stability and resilience has long preoccupied the ecologists (Holling, 1973). The subject has received renewed attention due to increasing concern over human-caused species extinctions and community impoverishment associated with habitat fragmentation. To date, the hypothesis that community stability to disturbance increases with community richness has met with mixed results in modeling and empirical studies, in part owing to differences in spatial and temporal scale and in how stability is measured.

Mechanical Disturbances

Most aquatic and terrestrial communities are constantly subjected to mechanical forces that reduce standing biomass at some scale. Avalanches, landslides, and debris flows remove soil, shear off and uproot plants, and bury plants and animals. High winds, snow, and ice uproot trees and break off branches and leaves that then bury other plants and animals. Ice in the near shore zone plucks and scours littoral communities. Floodwaters topple riparian vegetation and scour streambeds. Waves dislodge encrusting intertidal organisms and break down branching corals. Large animals break twigs and compact the soil as they move. Humans clear or clip vegetation and plow soils. Burrowing animals excavate plants and animals as they dig. In all of these cases, biomass is dislocated but not immediately chemically transformed or consumed. Most important, space occupied by living tissues is evacuated as those tissues are moved someplace else.

Thus, mechanical disturbances leave conspicuous openings and persistent biological legacies, such as large woody debris embedded in landslides, downed trees next to treefall gaps, floating wracks of detached marine plants and animals, or rubble piles of coral. Materials are often transported to a location where they act to create another disturbance. In turn, the legacy of biological debris from mechanical disturbances not only affects the rate and pattern of community recovery but also may influence the timing and location of subsequent disturbance events.

The spatial distribution of mechanical forces in the environment is highly nonrandom. Features such as substrate, topography, and standing biomass create persistent biophysical pathways in which specific mechanical disturbances are concentrated, thereby compounding existing physical environmental heterogeneity. For example, the location of avalanche paths is strongly associated with topography, geology, and lithologic structure. The impacts of severe wind storms on forest communities varies systematically with topography and soil characteristics as well as vegetation composition and structure (which depend, in part, on disturbance history). Wave energy is concentrated on jutting shorelines. Animal burrowing is concentrated in specific soils and sediments. In other words, many mechanical disturbance processes can have somewhat predictable spatial distributions.

Most mechanical disturbances operate indiscriminately (i.e., they do not target specific organisms, as would selective herbivory, for example) and their impact depends on the ability of organisms to withstand the mechanical force. Thus, mechanical disturbances often winnow biological communities. For example, snow avalanches apply a bending stress on trees in their path that is a function of the snow's density and the avalanche's mass and drag. Susceptibility of woody species to breakage (vs. bending) increases with tree size, leading to complex interactions between avalanche recurrence frequency and forest structure and composition in avalanche paths. Similarly, masses of attached barnacles and mussels in rocky intertidal environments become increasingly susceptible to detachment by waves as organism size and density increases. The same mechanical agent may create different kinds of disturbances depending on the size of the organism. In forests, for instance, woody stems may be most susceptible to breakage by wind

when they are very small or very large, whereas intermediate-sized stems may be the most susceptible to uprooting by wind (Everham and Brokaw, 1996). When impacts of mechanical disturbances depend on the size or density of organisms, this produces feedbacks that influence population dynamics and create pronounced spatial patchiness at scales well below that of the disturbing process (Levin, 1992).

Some mechanistic models have been developed to better understand and predict the interactions between physical forces and biological communities. A good example is the family of models relating slope or stream bank stability to plant root systems. Soils have low tensile strength but high compressive strength; conversely, roots have high tensile strength but are weak under compression. Thus the susceptibility of soil masses to shearing forces and associated landslides or bank collapses is strongly related to the composition, density, and size distribution of roots at different soil depths (Pollen-Bankhead *et al.*, 2009).

Physico-Chemical Disturbances

Physico-chemical disturbances such as extreme cold, prolonged inundation of terrestrial organisms, hypoxic episodes in aquatic systems, freshets in coastal waters, and releases of toxic compounds (e.g., biological exotoxins such as those produced by the dinoflagellate *Pfiesteria piscicida*), reduce biomass by imposing lethal physiological stress. Physico-chemical disturbances do not involve mechanical force (except perhaps in the case of extreme cold when tissue damage is due to the intracellular ice formation), and most physical and chemical disturbances leave dead tissues and organisms *in situ*. This contrasts with mechanical disturbances, in which space and resources are freed up through displacement of biological material. There are few studies comparing recovery processes under these two situations, but one might expect differences simply due to the presence or absence of residual detritus that could affect light, nutrient levels, and substrate quality. For example, management experiments in conifer forests of the western US comparing effects of mechanical thinning to controlled burning or both thinning and burning have produced similar forest structures but very different understory plant communities (Wayman and North, 2007).

Like mechanical disturbances, physico-chemical disturbances have organism-specific impacts because of species-, age-, and size-specific physiological tolerances to environmental extremes. Thus, like mechanical disturbances, physico-chemical disturbances operate as an environmental filter of biological assemblages.

As mentioned previously, much of the emphasis in disturbance studies has been on sessile organisms such as plants and benthic invertebrates. Some largescale physico-chemical disturbances may be somewhat distinctive in that they can kill large numbers of highly mobile organisms. For example, episodes of anoxia can cause massive fish kills in estuaries and lakes. Severe cold weather can selectively kill large numbers of birds. In these instances, the suddenness and magnitude of the events prevent animals from escaping, a phenomenon, which can also be observed during extreme wildfires.

Fire is obviously a special case of physico-chemical disturbance because biomass is both transformed and removed in the combustion process. Fire is also unquestionably one of the most pervasive and obvious disturbances in terrestrial ecosystems, and an enormous scientific literature has been devoted to the subject of fire events and fire regimes. It is discussed here to illustrate in more detail the concepts of disturbance mechanisms and disturbance regimes.

The occurrence of fire requires an ignition, fuel combustion, and spread, each of which in turn depends on many physical and biological factors, notably climate, weather, fuel structure and chemistry, and topography. The most important effects of fire are partial or complete combustion of above-ground vegetation, mineralization and deposition of plant tissues as ash and charcoal, extreme heating of the local atmosphere and topsoil, and killing of selected plants, seeds, spores, and animals both above and below ground.

Figure 1 presents a simple conceptualization of factors that influence fire dynamics at three distinctive spatial and temporal scales in Mediterranean-climate shrublands. The fire fundamentals triangle (Figure 1a), captures essential elements of the actual combustion process, which occurs at minute scales and depends on oxygen, heat, and fuel. The timing, size, and severity of a wildfire (or controlled fire) event, which may last hours to weeks and extend over hectares to thousands of square kilometers, depend on local weather, topography, and fuel bed. Finally, the fire regime of a landscape depends on complex interactions among climate, vegetation, and ignition factors operating over decades to centuries.

Fire creates strong biological patterns over a broad range of spatial scales. At the scale of individual plants, biomass combustion, soil heating, and nutrient removal can vary widely, imposing very fine-grained variation in mortality and postfire conditions that is manifested in equally fine-grained patterns of biological recovery. A coarser pattern can be created at the scale of entire population (vegetation stands). Fire severity and

vegetation removal can vary with topography, soil, vegetation, and wind conditions, and distance from source populations for seeds and animal colonists can influence community recovery. At still broader scales, landscapes are composed of fire mosaics, a patchwork of stands with differing fire histories and biotic communities. This landscape mosaic is one of the factors aiding in the long-term persistence of species with different fire tolerances. The spatial patterns from individual plant distributions to landscape mosaics all affect the location and severity of future fires and their ecological impacts.

Fires are obvious, discrete events, and research on wildfire history has provided many useful models and methods for characterizing temporal and spatial properties of disturbance regimes (Moritz *et al.*, 2009). Temporal properties such as time-since-fire (survivorship) and fire interval (mortality) are described using probability distribution functions, notably the Weibull and negative exponential distributions. Fire mosaics and their dynamics have been described using spatial Markov chain models, percolation theory, and spatial autocorrelation statistics. These quantitative characterizations are useful for describing changes in fire regime over time, for comparing different areas, and for estimating wildfire risk.

Disturbance by Herbivores and Predators

In many ways, consumers (and pathogens) have the same effects as other agents of disturbance in that biomass is removed and new opportunities for recruitment are created. There are some distinctive features, however, of disturbances by herbivores and carnivores. Most obviously, they operate at the relatively fine scale of individual consumers, and they leave a very different biological legacy than mechanical and physico-chemical disturbances because biomass is concentrated and converted into heat, new tissues, and discrete waste products. The waste products are frequently deposited away from the

Figure 1 Hierarchical model of fire controls at successively coarser scales of space and time. Connections between fire and individual controls indicate potential feedback loops (reproduced from Moritz MA (ed.) (1999) *Controls on Disturbance Regime Dynamics: Fire in the Los Padres National Forest*. Ph.D Dissertation, Department of Geography. Santa Barbara: University of California).

disturbed area. For example, frass from defoliating caterpillars in tree canopies falls to the soil surface. Shade-seeking ungulates in African savannas deposit a disproportionate amount of urine and feces under trees. Elk migrations lead to a net transport of nitrogen from summer ranges to winter ranges.

Foraging is also a far more selective form of disturbance than other disturbance mechanisms. Organisms (including humans) preferentially occupy specific sites and microsites and focus on specific plant resources, creating patchiness at many scales. Most plants are unpalatable to most herbivores, and selective herbivory by dominant grazers can exert strong, directional effects on community composition, structure, and ecosystem processes. These effects may be amplified by strong feedbacks among consumption, food quantity, and food quality. For example, moose in boreal ecosystems selectively browse nitrogen-rich deciduous species and avoid coniferous species. Over time, this promotes nitrogen sequestration in conifer litter and accelerates succession of deciduous to coniferous plant communities (Hobbs, 1996). Disease spread from infected to susceptible hosts and the development of resistance in infected individuals is somewhat analogous in terms of strong spatio-temporal feedbacks between the disturbance process and state of the system.

Many consumers act as mechanical, chemical, and biological agents of disturbance. Perhaps the most sensational example is that of beavers, which selectively fell trees, dam streams, and inundate floodplains. Similarly, burrowing animals such as pocket gophers can operate as “physical ecosystem engineers” creating pervasive changes in the abiotic and biotic environment by redistributing soil and nutrients, altering soil hydrology and canopy light regimes, and altering vegetation composition and dynamics.

Interactions among Disturbance Mechanisms

Disturbances can interact in complex, nonlinear ways across space and time. One disturbance may promote another, such as the occurrence of dry-season fire in Mediterranean-climate shrublands promotes flooding and debris flows during the ensuing wet season. Conversely, one disturbance mechanism may reduce the likelihood of another. For example, grazing reduces the likelihood of fires in grasslands and the likelihood of crown fires in some forest ecosystems. Nearshore communities that are heavily impacted by wave disturbance may also experience lowered rates of predation. It is not difficult to imagine many such interactions operating across a wide range of spatial and temporal scales.

Disturbances often play an important role in invasion and spread of exotic species. In Hawaii, for instance, invasion of the nitrogen-fixing shrub, *Myrica faya*, was facilitated when native vegetation was thinned by heavy ash deposition from a volcanic eruption. There is a growing list of examples in which disturbance promotes the spread of an invasive species and then that species initiates ecosystem changes that introduce new disturbance processes. For example, in the western US cattle grazing in shrub steppe promoted spread of the exotic grass, *Bromus tectorum*, and the presence of a dry grass layer then increased wildfire size and frequency in that system, in which fires were historically uncommon.

As mentioned in *Disturbance Ecology*, compounded disturbances, or disturbances of communities already stressed by abiotic or biotic forces, can have large and persistent effects on ecological communities if they occur in such rapid succession that they disrupt normal recovery processes. Repeated burning over a series of two or more years is a common means of converting shrublands to grasslands in semi-arid ecosystems. In a particularly dramatic example, Hughes (1994) describes the decline of corals in Jamaica owing to the combined effects of overfishing, two major hurricanes, and disease that caused mass mortality in sea urchins. These impacts appear to have collectively precipitated a massive phase shift from coral-dominated to algal-dominated reefs.

Humans as Agents of Disturbance

For many millennia, humans have been manipulating ecosystem processes with varying impacts on ecosystem function and species distribution. Human activities that create disturbances at spatio-temporal scales to which organisms are adapted generally do not effect long-term changes in community composition or structure. For example, shifting agriculture in the humid tropical forests, like hurricanes, creates small, temporary forest clearings and results in landscape mosaics within which most species can persist. In contrast, commercial forest cutting and cropland and pasture development are large and persistent disturbances that can produce regional extinction of species and require much longer periods for forest recovery (Attiwill, 1994).

Another widespread human impact has been to regulate or arrest disturbances such as fires, floods, or animal activities that create habitats on which some species depend. Even when human ecosystem manipulations are, by design, modeled after a particular disturbance, it is difficult to incorporate all disturbance-related changes in the environment. For example, forest harvesting can occur at the spatio-temporal scale of a natural fire regime, but the postfire nutrient pulse and legacy of dead snags are no longer factors in the recovering ecosystem.

As humans fragment terrestrial habitats through land-use conversion and aquatic systems through impoundments, diversions, dredging, trawling, and construction, permanent fragmentation of habitats is superposed on dynamic disturbance mosaics, causing changes in disturbance regimes. Such fragmentation can impede disturbance spread (e.g., the spread of fire or disease), alter disturbance regimes in remnant patches, and create edge environments with novel disturbance regimes. Local human activities can have large cumulative effects. For example, the building of roads alters the natural cycles of erosion and landslide initiation, whereas agricultural land use often leads to the concentrated nutrient inputs and changes storm flows in receiving water bodies. In fact, most human activities have the capacity for altering historical disturbance regimes in some way.

At the broadest scale, humans are changing global climate patterns, and nearly all mechanisms of disturbance and disturbance effects are ultimately tied to climate processes. Changes in disturbance regimes during global climate change are inextricably tied to other ecological responses to changing climate, affecting whether species can persist in their current

ranges or can invade new areas of more suitable environmental conditions. The tight coupling between biotic processes and structures and most disturbance patterns and processes – a recurrent theme in this article – creates complex feedbacks that could amplify or moderate the effects of global climate change on disturbance regimes, species, and ecosystems.

Introduction

The title of this article has many meanings. Economic analysis of environment and growth can mean many different things. In this article, the focus is on the following issues:

- What is economic growth?
- Will economic growth deteriorate or improve the environment?
- What is the role of environmental resources in economic growth?

The first question is typically answered by growth in gross domestic product (GDP) or GDP per capita. However, seldom is it explained why this is an interesting definition of growth. Of course, behind this notion of growth is the notion that GDP or gross national product (GNP) is a measure of well-being in society. It is therefore necessary to discuss what we mean by well-being and possible indices for such a concept. This will, of course, immediately bring us to a discussion of green accounting. There is a huge literature on this subject, but in this article the author will not try to survey those contributions but instead examine one particular formulation of the conceptual basis of green accounting in order to determine the difficulties in creating such an index (The discussion of these issues is based on Dasgupta and Mäler (2000) and Mäler (1999)).

The second question has been discussed in terms of so-called Kuznets curves – that is, empirically estimated relations between environmental quality and GDP per capita. The general finding for many pollutants is that a country with a very low income does not have much pollution but when the scale of the economy grows, for example, as measured by GDP per capita, emissions of these pollutants will increase. However, when the income per capita is high enough, the economy will reach a turning point and pollution will decrease with further increases in per capita income. This has been taken by the World Bank to mean that growth implies a win–win strategy. By growing, a country may in the long run obtain both increased material well-being and a better environment. Of course, this kind of analysis has been criticized, from conceptual points of view and also from econometric and empirical points of view. Once again, the literature is huge, and no attempt to summarize this literature will be done. However, some central issues will be discussed.

Finally, the role of environmental resources as inputs for the growth process has very seldom been studied. When Solow (1957) studied economic growth in the US, he found that most of the growth could not be explained by the two traditional factors of production (capital and labor), and he attributed the “unexplained” growth or the residual to technical progress. Later investigations by Dale Jorgenson, Zvi Griliches, and others (Jorgenson (1995a, 1995b)) provides masterful surveys of these issues) reduced the residual considerably (e.g., by using better

measurements of capital and by incorporating human capital), but it still remains quite high. This means that economists basically cannot account for all the productivity growth Western economies experienced during the past 100 years. To solve this problem, the theory of endogenous growth was developed during the 1980s and the beginning of 1990s. The main idea is to incorporate the externalities that research and development activities generate because the benefits from these cannot be captured completely by the companies that carry out these activities. These externalities will therefore contribute to growth without being accounted for in the usual way that we analyze productivity growth. However, there are other externalities that also should be accounted for, such as networking externalities or social capital (Dasgupta, 1999). In this context, there is one particular externality that is of interest – environmental or resource externality. Because environmental resources or natural resources in general often lack well-defined property rights, they are not transacted on markets and therefore not accounted for in the standard national accounts (SNAs.) This omission of natural capital in growth accounting studies may explain at least part of the residual.

Net National Product (NNP)

Aggregate measures such as GNP or GDP were not constructed to measure welfare or well being. They were aimed at measuring total monetary income in an economy and the total supply of goods produced in man-made facilities to provide economic planners with a database suitable for economic policies. However, despite warnings from many economists, GNP and GDP became used as indices of welfare. During approximately the past 25 years, economists have tried to define welfare and construct indices measuring welfare, and there is now a substantial literature on the subject. Instead of reviewing the literature, the author will discuss some issues not very much discussed. Furthermore, most of the literature is based on the assumption that the economy is following an optimal growth path, which is rarely a realistic assumption. Instead, we will assume that we are able to make forecasts arbitrarily into the future (The basic reason behind the assumption of an optimal growth path in much of the literature is that predictions become very simple. It will be shown that nothing essential will change when we switch to arbitrary allocation mechanisms).

The issues that will be discussed in this section are

- The notion of social well being
- Social well-being and population growth
- The search for a linear index – NNP as a marginal social cost–benefit criterion for elementary projects
- The search for a linear index – NNP as a measure of sustainable development
- Sustainable development and technical progress.

Social Well-Being

To discuss social well-being, it is useful to imagine a social planner who is in charge of planning an economy from now (date 0) to infinity. Koopmans (1960,1972a,b) has convincingly shown that the rational social planner should evaluate different policies with regard to how they affect the present value of the stream of future utilities, where the utility function is strictly concave and is a function of all the factors that influence the current well being. In other words, the social welfare function is written

$$W = \int_0^{\infty} e^{-\delta t} u(c(\tau)) d\tau \quad [1]$$

where $c(\tau)$ is the rate of consumption at moment τ . In principle, $c(\tau)$ is a vector, the components of which represent all the factors that affect well-being at time τ . However, it will not change any conclusions if we restrict ourselves to the interpretation that c is the aggregate consumption good.

One of Koopmans' conditions is that $\delta > 0$; that is, the discount rate must be strictly positive. The discount rate is necessary in order to be able to define a social well ordering over all possible future paths of utilities. However, this is the rate for discounting utilities. The rate for discounting consumption will in general be different and depends on the growth rate of consumption. The formula is

$$r = \delta + \eta g \quad [2]$$

where r is the consumption discount rate, δ is the utility discount rate, η is the elasticity of marginal utility of consumption, and g is the growth rate of consumption. It is clear that if δ is small and the growth rate is sufficiently negative, the social planner will want to discount future costs and benefits measured with consumption as a numeraire (i.e., the way we usually measure them in cost-benefit analysis) with a negative interest rate.

The strict concavity of the utility function guarantees an attitude in favor of equalization between generations. Holding everything else unchanged, a transfer from a rich generation to a poor generation will increase social welfare.

Mathematical Preludes

No in-depth mathematics will be used in this section and an elementary knowledge of calculus should be enough for the derivations made here. However, reading this section is not necessary for an understanding of later sections.

At time t , the economy has inherited assets from the past. Denote the vector of these assets K_t . Assume that the social planner can predict the future flow of consumption, given K_t . To do this, the social planner must know how these assets are going to be used (now and in the future) for consumption and accumulation of some of the assets and perhaps depletion of others (in particular, stocks of nonrenewable resources). Such predictions can be summarized by an allocation mechanism, which will be called α :

$$c(\tau) = \alpha(\tau, t, K_t), \forall \tau > t \quad [3]$$

Thus, the mapping α is the information the social planner uses for mapping forecasts.

Note that α is not only a function of the initial stocks but also of calendar time t . The reason for this is that there may be autonomous changing over time. If there is exogenous technical progress, for example, future predicted consumption will of course depend on this and α must therefore depend on calendar time. Other reasons for autonomous changes in the allocation mechanism may be trends in trade and forecasted changes in government policies. The author will discuss these issues later.

Given the allocation mechanism, the social welfare beginning at time t will be a function of the capital stocks at t , the allocation mechanism, and the calendar time. Thus,

$$W = V(t, \alpha, K_t) \quad [4]$$

V gives the social welfare achievable from the initial stocks K_t with the allocation mechanism α .

A marginal change in one of the stocks at time t will change the welfare, and this change is basically the marginal value of that stock; that is,

$$p_i(t) = \frac{\partial V(t, \alpha, K_t)}{\partial K_i} \quad [5]$$

where K_{it} is the stock of asset i at time t . In most of the literature on green accounting, the accounting prices are those that support an optimal growth path. The prices defined here do not. However, they reflect the true values of the initial stocks at time t .

It is practical to define the Hamiltonian H at time t as

$$H_t = u(c(t)) \sum_{i=1}^N P_{it} \frac{dK_{it}}{dt} \quad [6]$$

One can now show that (see Mäler (1999) for a proof)

$$\frac{dp_i}{dt} = \delta p_i - \frac{\partial H_t}{\partial K_i}, i = 1, 2, \dots, N \quad [7]$$

Although these equations are formally identical to the equations governing the costate variables in Pontryagin's maximum principle, they do not reflect any optimization except that the prices are the true measures of the marginal social values of the initial stocks.

Population and Welfare

So far, the author has neglected population changes in the discussion of social welfare. However, we know that humans have a finite life and new generations will be born. How do we take this into account when we try to formulate a welfare function for a society?

The simplest way is perhaps to assume that population changes exogenously in a predictable manner. Then, at each moment in time we can represent the welfare of the cohort by the utility of an individual with average per capita consumption multiplied by the number of individuals. However, this is seriously flawed in that fertility behavior is not exogenous. We now know that human reproduction behavior is governed by many social and economic factors. There are many studies showing that reproduction depends on the need for support during retirement, on the need for labor, on the need for risk diversification, and of course because children

can be regarded as consumption goods – that is, they give immediate welfare to the parents. Dasgupta (1993, 1997) provides discussions of these issues and references to empirical material. Thus, we should treat fertility as endogenous, something that depends on the economic system in all its characteristics. However, this is exactly what the allocation mechanism introduced in the previous section represents. Thus, the population at any particular future point of time is determined by α .

It is now easy to assume that the welfare function can be written

$$\int_0^{\infty} e^{-\delta t} L(\alpha(0, K_0)) u(c(t)) dt \quad [8]$$

However, this formulation does not take into account the fundamental difference between a potential human being and an actual human. What is the value of having one more individual to that individual? There is no reasonable answer to this question (see Dasgupta (1997) for an extremely interesting discussion of these issues). So far, we do not have an ethical base for assessing welfare to endogenous population changes.

A Marginal Cost–Benefit Rule

Define NNP with utility as the numeraire as the linearized Hamiltonian

$$NNP = u^i(c)c + \sum_{i=1}^N p_{it} \frac{dK_{it}}{dt} \quad [9]$$

If, instead, we choose consumption at time 0 as the numeraire, NNP is defined by

$$NNP = c + \sum_{i=1}^N \tilde{p}_{it} \frac{dK_{it}}{dt} \quad [10]$$

where $\tilde{p}_{it}$ is $p_{it}/u'(c(0))$.

Note that NNP is a linear index in all quantities, which makes it an interesting measure. A nonlinear measure such as the Hamiltonian is hopeless in terms of empirical applications. We cannot estimate all the consumers' surpluses needed to get an empirical estimate of the Hamiltonian.

Second, note that c is basically a proxy for all variables that affect current utility. Therefore, all these variables must be included in a generalized consumption set. Among these variables is the disutility of labor, which leads us to the conclusion that the wage bill, as long as the wage rate reflects the disutility of work, should be deducted. Immediate environmental damages should also be deducted (Mäler (1991) discusses these issues in detail.). In all these cases the damages should be valued at a rate that reflects the marginal disutility of the environmental damage with consumption as the numeraire.

Third, note that the investment part of the NNP must include net changes in all assets that will affect future well being. This means of course that the current narrow asset boundary in SNAs must be substantially extended.

Also note that the asset prices p_i must correctly reflect the social scarcity values captured by eqn [7]. These prices will not

always coincide with market prices. However, surprisingly often, market prices will capture the social scarcity values of assets that are transacted on markets. However, for all the ecological assets, the values must be estimated by modeling the ecological systems and their connectedness. There is a growing literature on these procedures (Freeman (1992) provides a good introduction).

It should be noted that the NNP measure so defined deviates radically from the United Nations recommendations. The NNP measure we have defined has one important property, namely, that if there is a small perturbation (so that price changes are small) of the allocation mechanism during a small time interval, and if this small perturbation increases the social well-being, then it will also increase NNP and vice versa (For a proof, see Mäler (1999) or Dasgupta and Mäler (2000)). This is what makes NNP interesting – a linear marginal cost–benefit criterion with which we can evaluate such perturbations (which henceforth will be called policy reforms).

Here, we consider discrete time, and the following example will indicate the use of the theorem stated previously. Assume that there is one allocation mechanism α and we consider a perturbation or policy reform $\Delta\alpha$ that for the first period prescribes the same allocation as α did for the second period. We compute the change in NNP when we make this policy reform and this change is positive. This can be interpreted as saying that the second period gives higher social welfare than the first period. By following the allocation mechanism α , welfare increases over time. However, note that this depends on the assumption that the prices do not change much.

This theorem can now easily be generalized to situations in which we take atemporal equity into account, and even population changes can be accommodated. The trick is to find the appropriate shadow prices.

The Hamiltonian as Constant-Equivalent Utility

In the previous two sections it was shown that NNP can be used as an index for conducting social cost–benefit analysis of policy reforms. However, the theoretical literature on green NNP has been directed toward a quite different end. It has argued that NNP measures “constant-equivalent consumption.”

It can be shown that the present value of a constant stream of utility equal to the Hamiltonian at time 0 is the maximum feasible constant utility stream that an economy can afford. This was first shown by Weitzman in the case in which the utility function is linear. In this case, NNP and the Hamiltonian coincide, and NNP gives the maximum constant-equivalent consumption.

However, a linear utility function is ethically flawed: It is insensitive to distributional issues. Furthermore, a large body of evidence concerning household saving behavior is at odds with linear utility functions.

Social Well-Being and the Concept of Sustainability

The World Commission (1987) defined “sustainable development” as an economic program in which, loosely speaking, the well-being of future generations is not jeopardized.

There are many possible interpretations of this. Consider the following:

- An economic development is sustainable if $dU_t/dt > 0$, where $U_0 > \lim U_t$ as t tends to 0.
- An economic development is sustainable if $dU_t/dt > 0$.
- An economic development is sustainable if $dV/dt > 0$, where $V_t = \int_0^\infty e^{-\delta t} U(C_t) dt$

It is clear that (a.) lacks ethical foundation. For example, it may be desirable to reduce U in the short run in order to accumulate assets so that the flow of U is still higher in the future. In this sense, (b.) offers greater flexibility in ethical reasoning: It permits initial sacrifices in the current standard of living, U (a burden assumed by the generation engaged in the reasoning), but requires that no future generation should have to experience a decline in its standard of living.

In contrast to (b.), the focus of (c.) as a notion of sustainable development is social well-being, V . The criterion permits the first generation to make initial sacrifices in V (relative to the past) but requires that social well-being should never decline in the future. Note that although (b.) implies (c.), (c.) does not imply (b.). In other words, (c.) is more general. In what follows, we adopt (c.) as our notion of sustainable development and develop criteria for judging whether a given economic program represents sustainable development.

One can now easily show that

$$\frac{dV}{dt} = \frac{\partial V}{\partial t} + \sum_i^N p_i \frac{dk_i}{dt}$$

The first term on the right-hand side is the autonomous change in V , reflecting exogenous technical progress or exogenous changes in terms of trade. This term has been discussed by the authors in the last section. For now, we assume that there are no autonomous changes. The previous equation simply indicates that the rate of change in welfare is equal to the value of the net investment in the economy. Thus, an economic program represents sustainable development if, and only if, the program net investment in the economy's capital assets is always nonnegative.

The result has intuitive appeal. It says that social welfare is higher today than it was yesterday if the economy is wealthier today. Here, an economy's "wealth" is interpreted as the accounting value of all its capital assets, and wealth comparisons are made at constant prices. In a famous article, Samuelson (1961) argued in connection with national income accounting that welfare comparisons should deal with "wealth-like" entities. Proposition 4 formalizes this insight.

Note, however, that what we have obtained is an equivalence result: the theorem cannot on its own tell us if sustainable development is feasible. Whether the economy is capable of growing wealthier indefinitely depends on, among other things, the extent to which different assets are substitutable in production.

This idea of examining changes in wealth dates back to Samuelson (1961). The connection to sustainable development was first suggested by Pearce and Atkinson (1993), although they did not derive the theorem rigorously and they did not interpret it as an equivalence result. The idea was then investigated by the World Bank, which published many

attempts to measure the value of net investment or genuine savings (see Expanding the Measure of Wealth (1997) and Kunte and Clemens (1998) for further details.)

Note that we cannot in general use NNP to determine whether the economy is on a sustainable path. Only if the prices are stationary is an increasing NNP equivalent to saying that the economy is on a sustainable path.

In conclusion, NNP can be used for cost-benefit analysis in situations in which prices do not change very much. In particular, in such a situation it may give some guidance as to whether social welfare is increasing or not. Note that there is no conflict between growth in the NNP and the concern for the environment. These concerns have been incorporated into the linear index. If the economy is on a path in which environment is degraded, this will be captured by the NNP, and it can be expected that NNP will decrease if the degradation is sufficiently large.

NNP is not useful for determining whether the economy is on a sustainable path because the relative prices will change along the path. Here, concepts related to wealth become more interesting. In particular, the value of the net investments in a time period gives a correct criterion for judging whether the economy is on a sustainable path. However, it is only a necessary condition. The sufficient criterion is that in each future period, the value of net investments must be positive. *A priori*, we do not know whether this is feasible.

Environmental Kuznets Curves

Since the early 1990s, economists and econometricians have been industrious in estimating empirical relations between GDP and environmental quality indicators. Typically, they have used cross-sectional data – country data for a particular year. For some quality indicators, they have found a relation that looks like an inverted U (Figure 1).

The interpretation is simple. Very poor countries with low industrialization are not damaging the environment much and as a result the environmental quality indicator is good (in this case, a low sulfur emission). When the country starts the growth process, the environmental damages will increase. When income per capita increases, the demand for a cleaner environment will increase, environmental legislation will be enacted, and the environment will improve. Because the curve is similar (but inverse) to the curves Kuznets (Economic Growth and Income Inequality, 1955) estimated for the relationship between income inequality and GDP per capita, they

Figure 1 An estimated empirical relation between GDP and environmental quality indicators.

have been known as the environmental Kuznets curves. (For an overview and examples of environmental Kuznets curves, see *Environment and Development*, 2 (4), October 1997.)

The breakthrough for this kind of analysis came with the *World Development Report (1992)*, which was devoted to the environment. The existence of these curves was taken to be an indication of possible win-win situations. By stimulating growth, one would also in the long run stimulate environmental regulations. It is clear, however, that the analysis is quite complex.

First, environmental Kuznets curves have only been established for a few environmental indicators. Second, at least earlier, the specifications of the relation between the quality measure and GDP per capita were quadratics, which almost certainly forced the curves to look like an inverse U. Third, the studies did not include environmental spillovers between countries. Fourth, they did not examine possible relations between indices of freedom and the environment. It has been shown that whenever people have had the right to voice concern about environmental degradation, the environment has improved, irrespective of the per capita income. Locally, in many cultures people have had a direct influence on, for example, local water pollution, which has improved even in very poor countries. It is therefore possible that the environmental Kuznets curves measure not only the effect of income growth but also growth in freedom.

However, most important is that the environmental Kuznets curves – if they exist in any meaningful way – are not optimal in any sense of the concept. Typically, a country would do much better to develop institutional and regulatory reforms for better environmental management than just trust that economic growth will automatically solve environmental problems. In this sense, the belief in environmental Kuznets curves and the associated belief in win-win situations are very dangerous.

Technological Change and Growth Accounting

Productivity growth as discussed previously is productivity growth in GDP in which the flow of services that are not transacted on markets are excluded (with of course some important exceptions, e.g., government output). Here, we are interested in productivity growth in NNP as defined previously. There is no reason why productivity growth in GDP would correspond to a similar growth of NNP (In fact, *Repetto et al. (1989)* showed that by including depreciation of oil reserves, deforestation, and soil erosion in Indonesia, the growth rate was reduced to approximately half the official growth rate in GDP). Furthermore, if, as *Jorgenson (1995a, ch. 1)* pointed out, changes in energy prices affected the observed productivity growth rate substantially, it should be clear that the utilization of other natural resources should also affect the growth rate of the total production. Thus, we should analyze the following issues:

Growth in NNP

The role of natural capital in the growth of NNP

The following calculations are very speculative, but the author hopes that someday someone will find it worthwhile to

study the empirical consequences from the analysis. The simplest possible model to demonstrate the main ideas has been used (which probably will be seen to be perhaps too obvious).

Let there be one aggregate good x which is produced with man-made capital K_x and with one input representing natural capital services, denoted γ . Thus,

$$x = f(K_x, \gamma) \quad [11]$$

Assume that the production function is homogeneous to degree 1.

The total output is used for consumption c , for investment in man-made capital $I = K_x$, and for investment in man-made capital for exploiting the natural resources $I_\gamma = K_\gamma$. Let the production function for γ be

$$\gamma = g(K_\gamma) \quad [12]$$

Thus, γ is an intermediary good in the system and x will correspond to GDP:

$$x = c + K_x + K_\gamma = c + K \quad [13]$$

Assume that capital is freely mobile between the two uses so that we can reasonably talk about the total capital stock $K = K_x + K_\gamma$. Then we can define the productivity growth in GDP as

$$\theta = \frac{1}{x} \frac{dx}{dt} - \frac{1}{K} \frac{dK}{dt} \quad [14]$$

Now, let the dynamics of the natural or ecological capital K_E be

$$\frac{dK_E}{dt} = \phi(K_E) - \gamma \quad [15]$$

Assume that there is an institutional failure in the economy so that there are no assigned property rights to natural capital and therefore no market transactions in K_E . This is of course the reason why investments in natural capital are not included in GDP.

NNP according to the definition in equation is

$$NNP = c + p_E \frac{dK_E}{dt} + \frac{dK}{dt} = x + p_E \frac{dK_E}{dt} \quad [16]$$

It is clear from eqn [16] that a positive productivity growth for GDP can be offset by depreciation of the stock of natural capital so that the productivity growth of NNP is 0 or even negative. In fact, if we assume that $\dot{K} = 0$, we have

$$\frac{1}{NNP} \frac{dNNP}{dt} - \frac{1}{K_E} \frac{dK_E}{dt} = \frac{GDP}{NNP} \theta + \frac{\dot{K}_E}{K_E} \left\{ \frac{p_E K_E \dot{K}_E}{NNP \dot{K}_E} - 1 \right\} \quad [17]$$

The last bracket in eqn [17] will surely be negative because of the overexploitation of the resource as a result of the institutional failure. Thus, this bracket will compensate for the positive productivity growth of GDP. In this case, because we know that the production functions are stationary, we know for sure that the productivity growth rate of NNP (if the production functions have constant returns to scale in K_x , K_γ , and K_E) must be 0. We can therefore conclude that even if measured GDP growth rates show a positive productivity

growth, this does not necessarily imply that NNP will show growth irrespective of factor inputs.

This result also follows from the observation that conventional SNA regards the inputs of resources as intermediary goods (if there are costs in producing them and it neglects them completely if they are supplied free of any costs to the production processes), and the estimation of an aggregate production function with only labor and capital as inputs, necessarily will be biased because resources are the basis for material production. Thus, the total factor productivity of GDP should be measured as

$$\frac{1}{x} \frac{dx}{dt} - w_K \frac{1}{K} \frac{dK}{dt} - w_v \frac{1}{v} \frac{dv}{dt} \quad [18]$$

where w_K is the value share of man-made capital and w_v is the value share of the resource input. This will necessarily be zero if the production function is linearly homogeneous and stationary. Thus, it may be that the neglect of resource inputs in the production functions is an important explanatory variable of the measured positive factor productivity growth. However, the only way to find out whether this is important is to carry out new empirical measurements. In conclusion, it does not seem reasonable to assume autonomous productivity growth in models designed to create a new accounting system for welfare measurements. Therefore, the argument for a nonstationary value function is not necessarily true.

Glossary

Bio-accumulation The accumulation of toxicants or other chemicals by successive organisms in the food chain.

Biological integration Organization of life functions in distinct, self-regulating units (cells, tissues, organs, organisms, populations, communities, and ecosystems).

Biosphere The region of the earth where life exists, including parts of the lithosphere, hydrosphere, and atmosphere.

Ecosystem A self-regulating assembly of communities of animals, plants, and microorganisms interacting with one another and with their nonliving environment.

Endocrine disruptor Chemical that interferes with the chemical communication (mainly performed by hormones) within an organism.

Remediation Removal of toxicants from a contaminated environment using chemical, physical or biological means.

Resolution The magnitude of a biological response due to a chemical insult.

Specificity The ability to relate a chemical effect to a distinct biological function or organism.

Xenobiotics Toxic substances not naturally produced within organisms.

Introduction

The manifest principles of ecotoxicology involve the application of the principles of toxicology to the environment: focused on human activity leading to the release of molecules such as polynuclear aromatic hydrocarbons (PAH), polychlorinated biphenyls (PCBs), xenoestrogens (XEs), chlorofluorocarbons (CFCs), pesticides, heavy metals, radionucleotides, greenhouse gasses (CO₂, CH₄), sulfur dioxide (SO₂) and oxides of nitrogen (NO_x) into the environment.

Biomonitoring is undertaken sometimes as the “prelude to remediation.” Remediation aims to remove potential toxic substances from a contaminated site, thus restoring ecosystem function as far as is reasonably possible following the removal of the ecotoxicity by biological, physical, or chemical means.

Molecular toxicology is the branch of toxicology (the study of the effects of manifestly poisonous substances on individuals) that adopts the biochemical approach to the understanding of the detrimental threats to life, often recognized by a range of morbid conditions in a variety of fauna and flora. Such pathology can be understood at a molecular level in terms of biomolecular damage undergone by such macromolecules as DNA (deoxyribonucleic acid: the genetic determinant mainly residing in the nucleus of the living cell), RNA (ribo-nucleic acid: responsible for transfer of the genetic message inherent in DNA structure sequence to the cytoplasm of the cell), and diverse proteins constructed from a choice of sequence of residues of 20 amino acids (obtained mainly from dietary protein hydrolysis during digestion).

It is the increased understanding of chemistry and its associated biochemistry that allows a meaningful prediction of toxicity of chemicals in all forms of life (ranging from bacteria and higher fungi to plants and animals including *Homo sapiens*). Although no meaningful distinction can be made between natural and manmade chemicals released into the environment, detoxifying enzymes such as the ubiquitous

oxygen-requiring enzyme family, cytochromes P-450, present in most forms of life, are useful biomarkers for constitutive or acquired tolerance to chemicals such as polycyclic aromatic hydrocarbons (PAHs), polycyclic halogenated biphenyls (PCBs), and xenoestrogens (XE). In the course of millions of years of biological evolution of species, survivors now display a range of such biochemical defenses against toxicants including the more recent pollutants released through industrial activity in processing and manufacturing industries.

Particular concern has been displayed recently for the contamination of the environment with endocrine disruptors (environmental hormones). These mimic the biochemistry of natural estrogens (such as 17 β -estradiol) and these have been associated with feminization of males, leading to displayed hermaphroditism in a few cases, in polluted environments. Some of these endocrine disruptors are derived from the release of industrial chemicals and are therefore referred to as xenoestrogens (foreign-compound estrogens). This is using the accepted nomenclature of xenobiotics as “foreign” or “manmade” chemicals, as contrasted with natural chemicals of which the environment, the diet, and all life is composed.

Several important concepts have been incorporated into the principles of ecotoxicology. For example, “hazardous chemicals” have the potential for causing harm to a variety of organisms, but the assessment of the risk to the biosphere posed by these chemicals must be based on consideration of the exposure (dose) to individuals, populations and communities as well as direct toxicity to the different species involved. Environmental exposure is not only determined by the quantity of a chemical released but depends also on the characteristics of a particular environment and the distribution of the biota in that environment. Soil that contains large quantities of clay minerals and humic substances might lead to immobilization of hazardous chemicals through absorption, while chemicals released in aquatic environments might be dispersed rapidly. In both cases, toxicity to the biota

living in these environments might be limited as exposure (bioavailability) is small. Also the distribution of different species in the environment is not random, but populations of a particular species are concentrated at particular sites (niche). For example, in soil some species are found in the litter that lays on the soil surface (epigeic and hemigeic species), while others frequent the deeper mineral soil layers (eudaphic species). It is clear that epigeic and hemigeic species are more likely to be affected by toxic chemicals that enter the soil environment from above than eudaphic species. Besides distribution, exposure will be determined by feeding patterns. Organisms that feed on prey that is likely to have accumulated the substance will be exposed to larger quantities of the toxicant than those that feed on substances that are relatively uncontaminated. Especially recalcitrant, low water soluble chemicals such as PCBs and organochlorines (DDT, for example) can be biomagnified in the environment to lethal concentrations higher up the food chain. Furthermore, toxicity of each hazardous chemical should be related to the metabolism of each major species present, as affected by the toxicant. Therefore, signs of toxicity need to be sought by a battery of methods before meaningful conclusions can be drawn on the environmental risk of a potential chemical released in the environment; environmental pollutants at a specified dose may cause changes in finely balanced ecosystems due to differential toxicity to different species and differential exposure of different species that inhabit the environment.

Much of ecotoxicology relates to the toxic effects of chemicals in natural ecosystems, but it must be remembered that man is an integral part of these ecosystems and effects on the other biotic components of the ecosystems of which he is part can affect him directly or indirectly. For example, in relation to bioaccumulation of toxic chemicals, substances like PCBs, chlorinated organopesticides, and heavy metals, are likely to accumulate (and cause toxic effects) in the human body because of the simple fact that man is high up in the food chain. Indirectly, man is dependent on the biosphere for the maintenance of the climate, purification of water and air, and the provision of a sustained food supply. Disruption of biological activity that impairs the capacity of the living world to fulfill these functions will ultimately affect humankind's well-being and survival. In this respect, therefore, human toxicology and ecotoxicology are of necessity closely interlinked.

Application of Different Scientific Disciplines to Ecotoxicology

Chemistry

Many different xenotoxins of many chemical structures are now ubiquitous in aquatic, terrestrial, and atmospheric environments. Most, however, are present at extremely low concentration. For example, there may be 60,000 molecular-species of "hormone-disrupters" such as the xenoestrogens that may be detected (albeit by remarkably sensitive detector systems that can respond to even a few hundred molecules for a positive identification). Nevertheless, most of these

xenoestrogens are extremely weak molecular-mimics of human estrogens, and many of these can, paradoxically, stop the estrogenic response of particular target tissues.

Proposed chemical approaches to ecotoxicology are often analytical in nature and seek to quantify the effect of each chemical species that can be identified and assayed so as to define the concentration-dependence of any hazardous substance and its consequent environmental or human risk. Quick tests for biohazards are essential, such as that achieved in the famous Ames Test for mutagenicity (and related carcinogenicity) in selected bacteria, for example, by the polyaromatic hydrocarbon, benzo(a)pyrene. Such mutagenicity (novel growth-behavior) due to genetic (DNA) damage may manifest as cancer in mammalian organs (because of loss of growth-control in particular tissues, due to subtle alterations in regulation of cellular growth by particular genes).

Biochemistry

Biochemistry studies the chemical processes that take place in living organisms. The main pertinent principle of biochemistry that can be applied to ecotoxicology is the modern concept of enzyme (biocatalytic proteins) regulation by molecular-intermediates of tissue metabolism in cells. Many xenobiotics (foreign chemicals unusual in nature) can interfere with the finely balanced biochemical reactions of living cells by perturbation of the web of molecular interactions necessary for life.

Additional problems are due to the molecular damage to DNA (deoxyribonucleic acid) and its related RNA (ribonucleic acid) along with cellular membranes (phospholipids that are readily destroyed by reactive oxygen species (ROS), generated by reactions of these chemicals with atmospheric molecular-oxygen). The ecotoxicity of ROS may, however, be ameliorated by antioxidants in the environment (and by dietary antioxidants such as vitamins C, E, A, and D as well as phytoestrogens in the diet).

Microbiology

The activity of microorganisms is at the basis for most functions on which life on this planet depends. Due to their almost limitless metabolic capacities, microbial communities are responsible for the transformation and recycling of organic and inorganic molecules in the environment. This activity results in the maintenance of nutrient cycles, the maintenance of soil fertility, and the detoxification of toxic substances in the environment. Furthermore, many microorganisms are intimately associated with every conceivable higher life form on this earth. They perform functions without which higher organisms could not function. Examples of this kind are organelles that have a microbial origin, including mitochondria, which are responsible for the energy generation in eukaryotic organisms (organisms with a true nucleus), and chlorophyll that allows algae and higher plants to convert carbon dioxide into sugars via photosynthesis. Other symbiotic interactions between microorganisms and plants that are of crucial importance for plant growth and nutrition are dinitrogen fixing microorganisms and mycorrhizae, which have close

associations with the roots of many plant species. In fact plant roots have adapted specially to accommodate for these microorganisms. Furthermore, microorganisms associated with the gut of animals provide essential vitamins that animals cannot synthesize themselves. On the negative side, microorganisms are responsible for causing a wide variety of diseases in plants and animals. Although this is negative from the viewpoint of the organism (or population) that is affected, disease causing organisms are important in ensuring that excessive population growth of particular populations is curtailed, thus ensuring the maintenance of an environment that contains a rich diversity of species. The interdependence between microorganisms and higher life forms means that toxic effects that affect either group of organisms can have important consequences for the other.

Biotechnology

Biotechnology is an applied science that aims to harness different life forms for the benefit of man. Agriculture, antibiotic production, and bioremediation are examples of such applications. Recent advances in molecular biology have given biotechnologists new tools to change the nature of life by genetic modification. This technology has resulted in the creation of organisms that would very unlikely have arisen in nature via normal mating and exchange of genetic material. It is now possible for humans to combine the genes of widely different organisms into one organism, giving this recombinant organism the means to express novel characteristics. Such "novel characteristics" include resistance to diseases and pests, resistance to pesticides, or the means to produce products that are of commercial or medical value. Whereas these organisms are of potential value to society, it is necessary to evaluate their environmental impact before they can be safely released into the environment. Therefore, with the advance of biological science comes the responsibility for biotechnologists to ensure that the integrity of the environment is maintained by ensuring that the biological functions that allow life on this planet to thrive are not impaired. Interestingly, recombinant technology has also opened the way to construct organisms that can be used to monitor the environmental impact of toxicants more sensitively. An important interface of ecotoxicology with biotechnology arises in the use of such genetically modified organisms as biomonitoring tools. However, the detection (and assay) of ecotoxins can be achieved by a variety of methods. An interesting example is the detection of carbon monoxide. This can be achieved using a caged canary (that responds sensitively to carbon monoxide in coal mines) or using an enzyme-based detector electrode that functions as a biosensor for this gas. A detailed account of biotechnological techniques for biomonitoring and bioremediation in relation to ecotoxicology can be found in the book by Lynch and Wiseman (1998).

Ecology

Ecology is the study of the interactions between organisms and their environment that determine the distribution and abundance of organisms. These interactions can be studied at

different levels of biological integration starting from individuals, which are part of populations, which are part of communities, which are part of ecosystems, which are part of the earth's biosphere. To gain a living from nature, humans have to understand the interactions that determine the abundance and distributions of organisms on which human life depends. This is not only important for the harvest of species from natural ecosystems by hunting, fishing, and or gathering of plant products, but also where the aim is to modify the natural environment to yield predominantly products that are of economical value as is the case in agriculture and forestry. Not only do we need to understand how we can most efficiently use the environment, but also increasingly we need to be aware of the impact of human activities on ecosystem function in general. Pollution of the environment by human activities (manufacturing, mining, waste disposal, transport, energy use, pesticide use, etc.) can have a large impact on ecosystem function via effects at all levels of biological integration. Especially since the scale of human activities has increased so dramatically over the past century there is a real danger that human activity interferes significantly with the basic biological processes of sustained life, including our own. Therefore, ecological knowledge applied to ecotoxicology aims to evaluate the consequences of human activity to ecosystem function, especially in relation to pollution caused by human activity.

Toxicology

Important principles of toxicology that relate to ecotoxicology include the concepts of extent of exposure, persistence, and distribution of chemicals in the environment. Subsequently predictions can be made on the toxicity of such chemicals to individual organisms or populations. The starting point of such analysis is often the chemical structure of each toxin, which will allow some prediction of the behavior of the chemical in the environment to be made. One of the best examples of this kind is the environmental impact assessment of the insecticide DDT. DDT is almost completely insoluble in water but readily soluble in fat. Furthermore, DDT and its degradation product DDE are highly persistent. Its low solubility means that it is easily dispersed in aquatic environments (in the case of DDT it is found at low concentrations all over the globe) and only accumulates in places with a high fat content (i.e., living organisms). Once it has entered living organisms, it persists and accumulates in the fat tissues of organisms that are higher up the food chain resulting in toxicity. For this reason, populations of both fish eating birds and bird eating raptors such as peregrines and hawks were badly affected by DDT, even in cases where they inhabited pristine environments.

Another aspect of toxicology is risk analysis. This quantitative topic is most easily studied when death rates within a population can be quoted. Whereas the rates can be determined experimentally for animals, plants, and microorganisms, the determination of the effects on the human population is inevitably more difficult to determine, and one of the few situations where effects are well known is the mutagenic effects of radionucleotides, resulting from

contamination caused by accidents at nuclear power installations or nuclear warfare.

Entry, Movement, and Fate of Pollutants in Ecosystems

Organic and metallic (including radionuclide) toxicants that enter the environment are regarded as pollutants of air, soil, and water. Their movement and transport is through air and water depending on their volatility and solubility, respectively. Soil and the detritus of sediments provide important solid supports for adsorption to regulate the movement and flow of the pollutants through terrestrial ecosystems, as well as influencing the localization and persistence of the pollutants in the environment. In this respect clay and humus particles that are electrostatically charged have an important role to play. Some organisms will take up the pollutant and concentrate them in their cells, a phenomenon known as bioaccumulation or biomagnification. This is particularly serious where the toxicant enters the food chain leading to progressive accumulation of toxic molecules higher up the chain, including humans. This is often the case with molecules that are relatively biologically inert such as heavy metals, PCBs, and organochlorine insecticides. Accumulation of such molecules in different species can lead to toxicity expressed as reduced growth, reduced fecundity, changes in behavior, susceptibility to diseases, or increased mortality. However, on the positive side, where there is storage of the pollutant in the cell, as is normally the situation with (heavy) metals, it is possible that the pollutant might be harvested and therefore removed from the environment. This especially applies to plants that hyperaccumulate metals in their tissues. The application of this process for the cleanup of contaminated land is known as phytoremediation. Also, many pollutants are biologically degradable and can therefore be detoxified. Both plants and mammals have a range of enzymes that are involved in detoxification of molecules that are potentially harmful to them (cytochromes P-450, for example), whereas the almost limitless metabolic capacity of a wide variety of microorganisms allows degradation of pollutants, especially hydrocarbons, into nontoxic molecules such as water and carbon dioxide. The stimulation of microbial degradation and metabolism of pollutants is known as bioremediation and is currently used to clean up contaminated land while microbial degradation of pollutants present in sewage and water is used in a variety of water purification systems. The fate of pollutants in the environment is therefore not only dependent on the molecular characteristics of the pollutant but also on a range of biotic and abiotic factors.

Biomonitoring

The ultimate goal of biomonitoring is to use biological effects resulting from chemical exposure for making predictions and deductions about the quality of the environment for life in general and human life in particular. Biomonitoring activities can be conducted on various levels of biological integration, over a period of time. Several overlapping terms are

commonly used in this process. It is worth noting that some of the tools are, strictly speaking, alternatives for chemical/physical methods to measure bioavailability of chemicals in the environment. In other words, they do not provide information on ecological effects *per se*.

- The term *bioreporter* is used for a molecular tool, often genetically modified cells, to transform the presence of a chemical into an easy measurable signal (e.g., luminescence).
- The measurement of biochemical and physiological variables in individuals or in their excretion products, providing information on exposure or damage, is indicated by the term *biomarker*.
- A *biosensor* or *bioprobe* is a physical device that allows the detection of a chemical as an electrical signal derived from a biocatalyst, such as an enzyme or an antibody.
- A *bioassay* is a toxicological test system in which the activity of a chemical is measured as an adverse effect on a population of a specific test species.
- A *bioindicator* is used to detect the effects of chemicals at the individual, population, community, or even ecosystem level.

Important in this respect is that when we move up to the higher levels of biological integration (populations, communities, ecosystems), effects are increasingly difficult to link to a specific chemical, even though the effects measured are of more importance. Furthermore, it takes an increasingly long time for higher levels of integration to respond to a chemical insult. For example, DDT took years to bioaccumulate up the food chain resulting in negative effects at the population/community level. On the other hand, chemicals that are apparently nontoxic at the lower levels of biological integration (carbon dioxide, chlorofluorocarbons (CFCs), sulfur dioxide, etc.) can have profound effects on all levels of biological integration. These chemicals might not directly affect biological processes but affect the chemical balance of the earth's biosphere (air, water, and soil). For example, greenhouse gases (carbon dioxide, methane, and water vapor) trap the sun's long wave radiation augmenting global warming, which could lead to profound changes of the world's ecosystems. CFCs contribute to the destruction of the earth's protective ozone layer, leading to an increase in harmful UV radiation that reaches the earth, resulting in increased lethal mutation rates and cancer. Sulfur dioxide and NO_x emissions lead to acid rain and acidification of soil and water, which in turn leads to the release of toxic quantities of metal ions in soil and water that kill both vegetation and animal life. An interesting example of this kind is the acidification of lakes in Scandinavian countries as a result of acid rain. The resulting lower pH of the lake water means that the water can contain a higher concentration of aluminum ions. However, the pH around the gills of fish is slightly alkaline, resulting in the precipitation of aluminum on the gills. This results in the impairment of gill function and suffocation of the fish. Even though Scandinavian lakes affected in this way look perfectly clean, they are devoid of fish.

A variety of specific tests have been employed to investigate the effects of chemicals on the environment. Generally the

Table 1 Some tests of chemicals that affect soil function

Retention capacity of soil and endangering of groundwater	Living space for plant production	Living space for soil communities
Growth (algae)	Dehydrogenase (<i>Bacillus cereus</i>)	Biomass (microorganisms)
Immobilization (<i>Daphnia</i>)	Nodulation (<i>Rhizobium</i>)	Enzyme activity (microorganisms)
Light emission (<i>Photobacterium phosphoreum</i>)	Shoot or root growth (various plants)	Nitrification (bacteria)
Mortality (fish, nematodes)	Yield (various crops)	Mortality (earthworms)
Mutagenicity (Ames, Umu)		Reproduction (collembola, earthworms)
		Respiration (microorganisms)

biotic effects used for biomonitoring deploy biota from the environment and expose them to different concentrations of the test chemical. Mortality of fishes, for example, has been used to assess toxicity of chemicals that are used in the soil environment (Table 1). In the soil environments a variety of effects can be investigated as to whether the retention capacity of soil would affect the toxicity of a chemical leading to leaching into groundwater or the living space for plant production and soil communities. In this respect, the assays relate to the effects on populations, gene products (enzymes and metabolites), or impact (plant bioassays) (Figure 1). However, the exciting development of recent years is the recognition that these effects are all controlled by genes and another method of biomonitoring is to use gene (DNA) probes (Figure 2). This option is very much in its early stages and the concept is to link a gene, which responds to a specific chemical or general effect, to a promoter DNA sequence and a reporter DNA sequence that either encodes for an enzymatic effect or any other specific signal. It is therefore possible to use genes, which respond to mutagenic substances with a light signal that is proportional to its mutagenic potential in the environment. Whereas this approach offers much promise, the reality is that it is complementary to the other methods currently deployed and should be used in conjunction with them.

A particular useful activity, which has been monitored in aquatic environments, is cytochrome P450. (Table 2). This is the terminal component of the mixed-function oxygenase, which catalyses expoxidation, hydroxylation, dealkylation, and desulfurisation, all critical in detoxification of toxic molecules in invertebrates and vertebrates (including humans). To date, more than 750 cytochrome P450 genes have been identified (Nelson, 1998). The cytochrome P450/A1 (CYP1A1) isoform is a biotransformation enzyme involved in a wide range of xenobiotic metabolisms (chemicals foreign to the natural environment) including metabolism of polyaromatic hydrocarbons (PAHs). Usually CYP1A1 has been used as a biomarker in fish and mollusks. The linking of this enzymatic function with its genetic control offers a great deal of potential for the biomonitoring of toxicology of both marine and freshwater ecosystems.

Biological Processes

The question can be raised why it is necessary to analyze complicated biological processes if the chemical in question can be measured directly using chemical or physical methodologies. There are at least three situations where

**Figure 1** Receptor/reporter gene assays; RE: responsive element.**Figure 2** Levels of perturbation measurement.

biomonitoring provides answers that cannot be arrived at using direct chemical measurements. The first use for biomonitoring is in situations where one wants to trace the chemical history of an environment. For example, the pH history of lakes can be deduced from the percentage acidophilous and alkalophilous species within the diatom communities preserved in sediment cores (Renberg and Hellberg, 1982). Similarly, pollen records preserved in soil provide information on past vegetation from which the past environmental conditions can be deduced. The second use of

Table 2 Hepatic cytochrome P450 1A (CYPIA) as a biomarker of organic pollution in fish*Fish species*

Atlantic tomcod (*Microgadus tomcod*), cod (*Gadus morhua*), Large-mouth bass (*Micropterus salmoides*), Rainbow trout (*Oncorhynchus mykiss*), Whitefish (*Coregonus lavaretus*)

Point sources of pollution

Chemical plants, incineration plants, industrial complexes, landfill sites, oil industry, oil spills, natural oil seeps, pulp mills, sewage

Diffuse areas of pollution

Bays, bights, estuaries, fjords, gulfs, harbors, lakes, offshore areas, river systems.

biomonitoring is a situation where the activity of a chemical is short-lived but the effects are persistent. For example, pesticides that disperse rapidly or are broken down rapidly cannot be measured easily, but their biological effects might persist for long periods. The insecticide deltamethrin is active only for a few hours after spraying, while effects on sensitive ground spiders and beetle fauna remain visible for weeks after spraying (Everts, *et al.*, 1989; Jagers op Akkerhuis, (1993). The third reason, and probably the most important one, for using biomonitoring is that effects of chemicals are dependent on the interactions that take place within the environment itself after their release. These interactions can be of a physical/chemical nature where the chemical is immobilized on to soil particles and is therefore not bioavailable. For example, the toxicity of metals, such as copper and zinc, in soil is determined by their bioavailability in soil. Both copper and zinc ions bind to soil minerals (mainly clay particles) and humic substances and as such are unavailable to the biota present in soil. Soils contain large quantities of these potential binding sites and therefore toxic effects of heavy metals are often buffered, even at relatively high concentrations. Because of this soil-buffering capacity, it usually takes some time of sustained metal inputs before metal ions become bioavailable at concentrations that are toxic. Both the mineral and organic fractions of soil interact with metal ions, providing negatively charged surfaces on to which cations can bind. Such adsorption displaces the cation that was previously counter-balancing the colloid's negative charge; hence the ability of colloids to adsorb ions in this way is known as the soil's cation exchange capacity (CEC). Heavy metals may also specifically adsorb on to hydrated oxides of aluminium, iron, and manganese by the formation of partly covalent bonds and can be chelated by solid-phase humic substances or by other organic ligands. The adsorption of metal ions is also affected by the soil pH. Acidification decreases the CEC of humic substances when carboxyl and ammonium groups will become protonated, reducing their capacity to bind metal ions. The increase in hydrogen ions will also increase the competition for negative binding sites, leading to the displacement of metal ions. Therefore, the size distribution of mineral particles, the amount of organic matter and the soil pH will to a large degree determine the metal buffering capacity of the soil (Gupta, 1991).

Besides physical/chemical interactions, chemicals interact with the biota present in the soil. For example, sustained use

of specific pesticides leads to the development of microbial communities that degrade the pesticide, reducing their half-life time and therefore their environmental impact. On the other hand, chemicals such as PCBs and organochlorides are likely to accumulate up the food chain resulting in high concentrations of residues distant from the point of release, thus increasing their environmental impact. As biological systems are not just collections of independent organisms but are strongly dependent on each other for their survival, it follows that chemical effects on one species can have important consequences for species that depend on the affected species. An example of this type of indirect effect is the decline of the gray partridge (*Perdix perdix*) in West Sussex, England. It could be shown that 48% of chick mortality was explained by the density of preferred insects. Given that reduced availability of insects is the key to the partridge decline, it was postulated that this might be due to increased pesticide usage, especially since there was a strong correlation between the partridge decline and increased herbicide use. The effect of the herbicides was shown to be indirect (they are relatively nontoxic to partridges), removing the host plants on which the insect larvae fed that were the food source of the partridge chicks, resulting in less insects and therefore less food for the partridge chicks. In conclusion, because biological effects are dependent on the behavior (movement, persistence, bioavailability) of the chemical in the environment, the sensitivity of biota and the role these biota play in ecosystem function, biomonitoring is often the only available way for monitoring chemical effects.

Early Warning Systems

Life as a whole can be seen as an hierarchical systems with distinct levels of biological integration. Going from a low level of organization to a high level of organization we can recognize cells that make up tissues, that make up organs, that are part of an organism; these organisms are arranged in populations that form part of communities, that are ultimately part of ecosystems. In general, it can be said that biological systems are at each level of organization buffered to resist change in overall performance by adjusting the components that make up that level of integration. The result of these buffering effects is that effects at lower levels of integration are dampened so that they do not affect higher levels of integration. Only when the buffering capacity at a certain level of integration is exceeded will the next level of integration be affected. This implies that toxic effects can be measured at the lower levels of biological integration before they result in effects at higher levels of integration. Because the aim of biomonitoring is "to provide a means by which (impending) changes in ecosystem function can be detected," compensatory effects at lower levels of integration can provide an early warning system of adverse chemical effects. A good example of such an early warning system is the thinning of bird eggshells as a result of DDE (one of the metabolites of DDT). DDE affects Ca deposition in eggshells (physiological change). However, only when egg shell thinning is in excess of 16 to 18% will this lead to a decrease in breeding success of the birds affected. Eggshell thinning is therefore an early warning system for population

change. Not all bird populations are likely to be affected as DDE accumulates up the food chain. Only birds that are at the top of the food chain (raptors and fish-eating birds) will be affected in the first instance. However it can be assumed that if DDT use had continued, the decline in raptors and fish-eating birds would eventually have resulted in community changes.

What is important in this context is to recognize which factors determine the buffering capacity at each level of biological integration. These factors can be used profitably in biomonitoring. It is, however, important to recognize that if we are interested in impending changes at the community level, it is probably most sensible to look for changes that are occurring at the level below (i.e. the population level). Similarly, impending population effects are most profitably investigated using effects on individuals. However, changes at the organism level will be too sensitive for making reliable predictions at community level and above. This simple fact is often overlooked in biomonitoring where current molecular technology has allowed precise investigation at the lowest levels of integration. These techniques allow the development of sensing systems that pick up changes that occur at the molecular and physiological level. Whereas these approaches are valuable for medical purposes in which we are interested in warning systems that help prevent problems at the individual level, they are inappropriate for monitoring ecosystem changes, in that they are far too sensitive. In choosing the most appropriate monitoring tool, one has to evaluate its relevance, reliability, robustness, responsiveness, and reproducibility. These factors, known as the 5 Rs, will differ according to level of biological integration and the composition of biological units that make up that level. It is unlikely that an environmental monitoring system will be "a freeze dried, talking bug on a stick" (van Straalen, 1998). As interactions that govern processes at each level of biological integration become apparent, new and more appropriate biomonitoring tools will become available. The simple fact that only a fraction of the species that make up "biological life" are classified shows that we have still a long way to go.

Specificity and Resolution

Within each level of biological integration the biological units that make up the level of integration display different degrees of specificity and sensitivity to different forms of (chemical) stress. With the term *specificity* it is meant that a biological effect can be related to a specific stimulus. For example, inhibition of the enzyme ALA dehydrogenase is only induced by lead, while induction of an immune response might be triggered by a wide variety of causes. The term *resolution* is used to indicate the ability of a bioindicator to respond to small environmental changes. For example, a specialized predator at the top of a food chain is a more sensitive indicator of bioaccumulation of persistent pesticides than omnivores with a varied diet. Although it seems that sensitive indicators with a great resolving power hold the greatest promise for biomonitoring, these properties are likely to result in overcaution and false alarms. In general, it can be said that indicators at lower levels of biological integration are more sensitive than characteristics that relate to higher levels of biological

integration. Therefore, indicator species are more sensitive than diversity indices, for example. What makes a "good" bioindicator will depend on the information that is required. Looking at a "soil ecosystem" for example, the biological components that make up the system consist of plants, vertebrates, invertebrates (insects, earthworms, nematodes, mites and springtails), protozoa, bacteria, and fungi, all of which perform crucial roles in the maintenance of soil ecosystem function. When the system is exposed to a potentially toxic chemical the ability of each population to cope with this exposure will depend on genotypic plasticity within the population, phenotypic plasticity, mutation rate, metabolic capacity, and level of exposure. Genotypic plasticity will be high in microorganisms that multiply fast and can acquire resistance genes via mutations or by acquisition of plasmids carrying resistance genes. As a result, adaptation of microbial communities to chemical stress is likely to be high. Furthermore, because of the almost limitless metabolic diversity displayed by microorganisms, populations that contribute to the detoxification of a toxic chemical might increase rapidly (comparable with the activation of the immune system as a response to foreign molecules/organisms that enter a higher organism). Other organisms (plants, vertebrates, and invertebrates) that have a large phenotypic plasticity might respond to a chemical insult by avoiding those areas that are most contaminated. Furthermore, spatial distribution of the biota in the soil environment and their mobility will both determine exposure and therefore toxicity. Only when there is a clear understanding of "normal" distribution and diversity of the biota in a given ecosystem is it possible to relate biological patterns to the effects of a toxicant in a meaningful way.

Because of the biological complexity of ecosystems, efforts have been made to classify organisms not according to species but according to similarities in life strategy. Biological life can be roughly classified by the way organisms spend resources on their offspring. Organisms that invest in large numbers of offspring (giving each limited resources) are termed r-strategists, while those species that invest in few offspring (each of which is provided with ample resources) are termed K-strategists. Looking at the spectrum of life, there is a general trend that large organisms are K-strategists, while small ones are r-strategists. Although this is true to a large extent, within a certain body class size there are organisms that have adopted r- or K-type survival strategies. For example, mice are typical r-strategists (they have many large litters each year), while bats produce every two years a single offspring, making them typical K-strategists. Not surprising, K-strategists are characteristic for stable, climax environments while r-strategists are characteristic for unstable pioneer environments. In terms of "stress," K-strategists are adapted to cope with biological stress (competition, predation, etc.), while r-strategists are adapted to cope with physical/chemical stress but are not good at coping with biological stress. In general, it can therefore be stated that r-strategists are insensitive to chemical stress, while K-strategists are sensitive. When an ecosystem is challenged by toxins (pesticides, for example), the r-strategists (the pest organisms) are the first to develop pesticide resistance, while the K-strategists (nonpest species) will disappear. The reason for this might be found in the fact that large numbers of offspring provide large genetic variability leading to rapid selection of

the best-adapted individuals. Chemical/physical stress on an ecosystem will therefore lead to a shift in the balance between r- and K-strategists in favor of r-strategists. This principle has been used successfully to monitor environmental pollution and disturbance using colonizer/persister (c-p) indices applied to nematodes (Bongers, 1990) or perturbations of rhizosphere microbial communities (De Leij *et al.*, 1993).

Another useful way of looking at communities and ecosystems is by classifying the organisms that inhabit that ecosystem by their "trophic function." Using this approach, organisms can be classified (aboveground) as primary producers (plants and algae), herbivores, predators, and top predators, while organisms that feed on a variety of food sources are classified as omnivores. In general, food chains have no more than four trophic levels because less and less energy is available higher up the food chain. Furthermore, dependence of predators and top predators on exclusive feeding sources make them vulnerable to perturbations lower down the food chain. Using the concept of trophic levels, it can be argued that specialized feeders are more sensitive to environmental stress (when this stress affects their food source) than organisms that are less specialized. Not surprisingly, when recalcitrant chemicals enter the food chain it is the specialized feeders (for example, peregrines and sparrow hawks that feed exclusively on birds) that are the first to be affected by toxins. Beside the fact that they are exposed to relatively high levels of a pollutant, these organisms are often very skillful specialized hunters. Any impairment of these skills due to a toxin will result in starvation. Therefore, these species can be sensitive bioindicators of toxins, even at sublethal concentrations.

Another important ecological concept that can be used to simplify ecosystems in a meaningful way is the concept of keystone species. The idea is that even though there is dependency between all species that are involved in a certain food web, some species are more important than others. It is important in this context to make a distinction between dominant species that derive their importance to the ecosystem in terms of biomass or energy flow and keystone species. Keystone species are often relatively rare but have a major impact because of their key regulatory function in the system as a whole. This is because these species are involved in more links or interact with parts of the ecosystem that maintain living conditions for a wide variety of other species. In other words, the species diversity of an ecosystem is determined in large part by a few keystone species on which many others depend. A detrimental effect on these species will result in the collapse of the whole ecosystem (or at least a large part thereof). Several different categories of keystone species have been recognized, such as keystone predators, keystone prey, and keystone habitat modifiers. One of the best-studied examples of the importance of keystone predators is the starfish (*Pisaster*) and predatory whelks (*Nucella*) in pools along the rocky inter tidal zone. Removal of these predators led to the disappearance of 80% of the prey species and the nearly complete dominance of the prey community by mussels (*Mytilus*). Sea otters (*Enhydra lutis*) have also been labeled as keystone species as they limit the density of sea urchins, which, in turn, eat kelp and other macro algae that provide the habitat for a large variety of species. Without sea otters the sea

urchin population explodes resulting in the destruction of the kelp forests leading to the loss of habitat for those species that depend for their survival on the kelp forests for reproduction, shelter, and food. The way keystone species are affected by toxins is an important consideration in ecotoxicology, because they represent the Achilles' heel of an ecosystem. Not surprisingly, keystone species such as earthworms and honeybees are often used in toxicity testing because they are important for ecosystem function in general.

Clearly a negative effect on ecosystem function is often due to alterations of complex interactions within the ecosystem itself. In most cases, toxic effects are buffered due to the compensating capacity of an ecosystem. However, occasionally toxic effects can affect species that are responsible for essential functions in that ecosystem. Further insight in the way that different species contribute to ecosystem function is an essential requirement for the development of the most appropriate biomonitoring tools for assessing the ecotoxicological effects of chemicals.

Conclusion

Currently there is growing concern internationally about environmental toxicants affecting biodiversity and human health. Biodiversity has come to the fore by the United Nations meetings, the first of which was in Rio de Janeiro in 1992. The medical profession is increasingly concerned about a range of conditions that might be induced by chemicals in the environment. This is resulting in moves to increase legislation. The study of ecotoxicology seems therefore certain to grow in importance, as well as there being a stimulus to prevent problems occurring in the first place via the development of clean technology and stimulation of sustainable land use. On the other hand, ecotoxicology can help to identify existing pollution problems, which in many cases can be cleaned up using a variety of remediation strategies.

Glossary

Bottom-up versus top-down Description of the forces governing overall community structure: availability of nutrients is a bottom-up force and predators are a top-down force. Both may regulate, for example, the amount of standing plant biomass, or whether a lake is clear or murky.

Density dependence A common ecological phenomenon whereby the effect of an entity (e.g., a species' rate of population growth) is a nonlinear function of its density. So, for instance, for the same input of energy, a species may increase in population rapidly at low and intermediate densities, but because of physical interference while foraging, more slowly at higher densities.

Primary productivity The *in situ* transformation of chemical or (more commonly) solar energy into biomass, producing the primary energy source for the rest of the community.

Selection regime A situation in which a particular set of evolved traits is favored. Here, the newly established

population evolves in a different direction from the ancestral population.

Teleconnections Atmospheric interactions between widely separated regions that have been identified through statistical correlations. For example, El Niño involves large-scale changes in climatic conditions over the Pacific that are linked to increased winter rainfall in the southwestern United States through a teleconnection.

Trophic inputs Energy entering a community *via* pathways other than local primary production, and often at higher levels in the food chain. For example, nutrients from salmon carcasses are a periodic trophic input to the forest community adjacent to salmon streams.

Upwelling An ocean phenomenon whereby cooler, more nutrient-rich water rises up from the bottom of the ocean to the surface. This occurs where currents of contrasting temperatures meet. The extra nutrient influx allows for specific and rich upwelling ecosystems in these areas (e.g., off the coasts of Chile and Peru, and southwest Africa).

Introduction to El Niño-Southern Oscillation

The El Niño-Southern Oscillation (ENSO) is a climatic and oceanographic phenomenon centered in the Tropical Pacific. Extreme oscillations in ENSO are termed “El Niño” and “La Niña” events, depending on phase (see [Figure 1](#)) with El Niño generally being the more extreme deviation. Such ENSO events, which have historically occurred every 2–7 years on average, can have dramatic, cascading, and long-lasting effects on terrestrial and marine ecosystems spanning numerous regions worldwide.

Some recent models suggest that predicted global climate change will result in more frequent and more extreme El Niño events ([Tudhope et al., 2001](#)), though there are still uncertainties in the exact nature of the predicted changes. Evidence from corals suggests that the amplitude of modern ENSO events is significantly greater now than during any other period in the past 130,000 years ([Tudhope et al., 2001](#)), while evidence from Galapagos diatoms indicates that the most recent 50 years have had the warmest sea-surface temperature (SST) of any 50-year period in the past 1200 years for the eastern equatorial Pacific Ocean ([Conroy et al., 2009](#)). However, the complexities of modeling the interactive factors contributing to the onset, frequency, and severity of ENSO events currently preclude predictions about the magnitude and direction of future changes to this oscillation ([Collins et al., 2010](#)). In recent years, the 1997/1998 record-breaking El Niño followed only 15 years after the previous record El Niño event of 1982/1983. The 1997/1998 El Niño developed so quickly that each month set a new record for warm SST based

on records dating back to the middle of the nineteenth century ([McPhaden, 1999](#)).

Extreme ENSO events change weather patterns, increasing precipitation in normally dry areas and reducing precipitation in normally wetter areas, as well as increasing SST and reducing nutrient upwelling in the eastern Pacific Ocean. ENSO events have been shown to influence ecosystem functioning ([Curran et al., 1999](#)); changes to ENSO may therefore affect the long-term biodiversity of large parts of the planet, especially when it is appreciated that climatic changes associated with both El Niño and La Niña occur in some of the most biodiverse areas of the planet ([Holmgren et al., 2006](#); see [Figure 2\(a\)](#) and [2\(b\)](#)). Here, we survey some of the best-documented effects of ENSO events on biodiversity. We have chosen to organize these effects by the direct ENSO-induced change (fire and drought, increased precipitation, increased SST and changes in ocean currents) rather than the more common biome-based approach.

Expected Effects

If the climatic effects are large enough (e.g., drought-induced fire, see [Observed Effects: Fire and Drought](#)), ENSO events can be characterized as cyclical disturbance events. If moderate in intensity and infrequent, such disturbances could theoretically increase local diversity over that expected under steady-state conditions (the Intermediate Disturbance Hypothesis; [Connell, 1978](#)). So, past ENSO cycles might have encouraged

Figure 1 Time series of the Multivariate ENSO Index (MEI) from 1950–2010. The MEI is based on six observed variables over the Tropical Pacific: sea level pressure, surface zonal and meridional wind components, sea-surface temperature, surface air temperature, and cloudiness. Positive values of MEI (red) indicate warm, El Niño conditions, while negative values of MEI (blue) indicate cold, La Niña conditions. For more information about the MEI, see Wolter and Timlin (1993, 1998).

increased local species richness, though retrospective studies are difficult.

Long-lived organisms (e.g., trees) may be adapted to an evolutionary history of repeated, within-lifetime disturbance. Regardless, rapid changes in ENSO intensity can increase environmental variation beyond a species' threshold, causing a die off. If disturbances occur at too high a rate relative to recruitment, successive decimations can produce severe population bottlenecks, increasing the probability of both deterministic and stochastic extinction.

In contrast, short-lived organisms that can evolve within ENSO cycles may be constantly adapting to changing conditions. Microcosm experiments suggest that intermediate temporal variation in environments (e.g., oscillations between one benign and one 'harsh' environment, such as El Niño-induced drought) may increase genetic variation, though with less of an effect than spatial heterogeneity (Kassen, 2002). However, a sharp increase in amplitude and frequency of temporal disturbance can erode genetic variation, with evolution toward either generalist phenotypes that do well under both regimes, or, if the harsh environment is severe enough, specialist phenotypes adapted to the harsh, though rarer, environment (e.g., adapted to El Niño-induced drought years). ENSO events are also likely to have species-specific effects on short-term evolutionary dynamics. For example, on the Galapagos Islands trait evolution of finches changed rapidly in response to the strong El Niño events of both 1976/1977 and 1982/1983; for instance, drought killed more females than males of one species, leading to interspecific hybridization and subsequent population genetic changes (Grant and Grant, 2002).

Through changes in current movement and increased SST (see Observed Effects: Increased Sea-surface Temperature), regular ENSO events also increase the potential for long-range dispersal. Such migration and gene exchange often decreases geographic genetic structure. However, rarer and more extreme events may cause entirely new habitats to be colonized, especially by species with plankton. This could promote speciation by creating separated populations in novel selection regimes. As well, depending on how they affect the complexity of the new habitats, newly introduced species can either

positively or negatively influence species richness in existing communities (Crooks, 2002).

Observed Effects

Fire and Drought

Although fires are not new to wet tropical areas, their rate of occurrence has generally been on a scale of hundreds to thousands of years so that many forests and tree species are ill-adapted to frequent large-scale fire events (Cochrane, 2003). The observed and projected increase in ENSO-induced wildfires means that forest fires are now considered to be a major threat to tropical biodiversity (Laurance, 2003).

The Brazilian Amazon and Western Indonesia, particularly eastern Borneo, are two of the areas worst affected by ENSO-induced forest fires; they also harbor among the most diverse floras and faunas in the world. El Niño-associated fires were described for East Kalimantan (Indonesian Borneo) as early as 1914, but until recently these were restricted in scale (Brown, 1998). The first recorded major burning event in East Kalimantan was during the 1982/1983 ENSO event, which caused a conservative 5.5×10^9 US\$ of damage, not including ecological costs (Siebert *et al.*, 2001). The 1997/1998 El Niño-induced fires in East Kalimantan were even larger, costing 1.4 billion US\$ for smoke-related damage alone. These fires mainly occurred in recently accessed logging concessions (Siebert *et al.*, 2001). In the Amazon, 20,000 km² of forest burned during the extreme 1997/1998 El Niño; satellites revealed almost 45,000 individual fires, most of which were sparked by humans (Laurance, 1998). An additional 1.5 million km² of forest became susceptible to burning, but did not burn because of insufficient ignition sources (Nepstad *et al.*, 2001). However, frontier expansion is bringing people and thus ignition sources closer to forest tracts. Although the effects are poorly known in the Amazon, an estimated 50% of the remaining forests have already been affected by fires, which have caused more deforestation than intentional clearing in recent years (Cochrane *et al.*, 1999).

El Niño and Biodiversity hotspots

(a)

La Niña

(b)

Figure 2 ENSO and biodiversity. A Robinson projection of the world with areas most greatly affected by the two phases of ENSO, El-Niño (a) and La Niña (b), highlighted (Allan *et al.*, 1996). Superimposed are the dark red terrestrial areas designated as world biodiversity “hotspots” (Myers *et al.*, 2000). The overlap is fairly strong, at least in part because both ENSO effects and species are concentrated in the tropics.

Deforestation fires can smolder for up to a week (Figure 3), and can destroy soil-stored seed, reduce the number of resprouting plants, and lead to a longer-term decline in soil fertility due to combustion of organic materials. Repeated burning can deplete the seed supply and cause additional mortality to upper-canopy trees. Typical low-intensity ground

fires kill nearly 40% of trees less than 10 cm in diameter at breast height (dbh) and most vines and ground forbs. Mortality is highly species-specific (Slik, 2004). With multiple burns, large fire-contacted trees have no survival advantage over smaller trees (Laurance, 2003). Owing to the lack of a seed bank for climax species in the tropics, their regeneration

Figure 3 Lowland tropical Dipterocarp rainforest, Wanariset, Kalimantan, during the 1997–1998 El Niño fires.

following burn events depends on sapling survival, resprouting and the seed rain from surviving trees. Sapling survival, however, can be very low following burning. In burned forest in East Kalimantan sapling density was only 2.5% of that found in adjacent unburned forest (Cleary *et al.*, 2006b). Resprouting is also highly species-dependent, in part due to changed light conditions (Slik, 2004); whereas a few rainforest species (e.g., *Fordia splendissima*) are able to resprout profusely after burning, many others fail to resprout at all. Regeneration will therefore, to a large extent, depend on surviving trees and areas of unburned forest that tend to be located in low-lying topography such as forest flood plains (Slik, 2004). Multiple fire events reduce the area of remnant unburned forest because fires tend to become more probable along previously disturbed edges. Under a frequent fire regime, low-diversity stable grasslands can develop. Under a less frequent burn regime, novel pioneer-dominated forests (e.g., dominated by typical pioneer genera such as *Macaranga*, *Mallotus*, or *Trema*) may replace the normal dipterocarp forests, with unknown effects on forest biodiversity.

Primary forests are less susceptible to forest fires than logged and already burned forests because they are more humid (Brown, 1998; Cochrane, 2003) and contain less dead wood (Nepstad *et al.*, 2001). Therefore, during 1982/1983 and 1997/1998, logged forests suffered greater tree mortality than unlogged forests, and fire intensity was directly related to the intensity of logging (Siebert *et al.*, 2001).

Animal responses to fire are still poorly understood. Small mammals, reptiles, and amphibians, for example, were reported to increase in abundance and species richness following forest fires in South America while birds and insects declined (Cochrane, 2003; Barlow *et al.*, 2002; Fredericksen and Fredericksen, 2002). Animals negatively affected by forest fires in Amazonia included slow species with poor climbing ability, cavity-breeding birds, army ants, understory wasp colonies, and leaf-litter invertebrates. Affected forests were also conspicuously silent, generally lacking in the usual vocal activity of monkeys and birds. The birds most affected were uncommon species, habitat specialists, and species that avoided disturbed areas (Laurance, 2003). All of the insectivorous guilds were severely affected by fire, of which the dead-leaf-gleaners and ant-followers were worst affected.

In Borneo, butterfly species richness declined dramatically following forest fires; specialist and restricted range butterfly species recorded before the 1997/1998 ENSO event were also much less likely to return to the regenerating forest than were generalist and wide-ranging species (Charrette *et al.*, 2006). In addition to this, the allelic richness of populations of one species, *Drupadia theda*, that survived the fires, was substantially lower in burned forest and a small unburned isolate than in a large unburned isolate (Cleary *et al.*, 2006a).

In general, while large frugivores and other vertebrates were adversely affected by single burn events in the Amazon, most primary forest specialists across all guilds were extirpated from twice-burnt forest (Barlow and Peres, 2006); we have found the same extreme effects of multiple fires for Bornean butterflies and dragonflies (Cleary *et al.*, 2004).

Even without direct burning, increasing El Niño events could affect tropical forest biodiversity. In Panama, there is a strong relationship between El Niño events, which increase fruiting in rainforest trees, and subsequent famine-induced population changes among frugivorous mammals when the following year is dry (Wright *et al.*, 1999). ENSO-induced drought can also increase tree mortality, particularly in previously disturbed forest (Harrison, 2000; Slik, 2004). In Northern Borneo, El Niño-related drought in a small forest fragment (<6500 ha) led to mass local extinction of fig wasps, thereby disrupting the important mutualism between fig wasps and their keystone fig hosts (Harrison, 2000). Also in Borneo, we found that butterfly species richness was not only substantially lower in burned forest, but also in small (<5000 ha) and large (>100,000 ha) unburned isolates surrounded by burned forest than in continuous forest or forest sampled before the 1997/1998 El Niño (Cleary, 2003).

Increased Precipitation

Water as a Limiting Factor

ENSO-induced increases in precipitation act as resource pulses for primary producers in water-limited ecosystems. The expected effect of such pulses is an immediate increase in ephemeral plant density, with a delayed increase in perennial plant abundance, and herbivore and predator abundance. Over the short term, local biodiversity can change dramatically, as in the Flowering Desert of Copiapó, Chile. For example, normally arid islands in the Gulf of California experience an increase in plant cover from 0–4% in non-El Niño years to 54–89% during El Niño events (Polis *et al.*, 1997). While annual plants account for the majority of ground cover increase, perennial plants also respond to increased water availability by increasing growth, and flower and fruit set production. Seed banks in arid and semiarid regions have been observed to experience a 5–10 fold increase during ENSO-induced wet periods. The species composition of these plant communities also changes during wet years, with normally uncommon or absent species becoming dominant. Thus, the species richness apparent during the common, dry years is not representative of the overall diversity contained in the seed bank (Gutierrez *et al.*, 2000).

As well as such short-term changes in plant communities, ENSO-associated increases in precipitation can also aid in the

recruitment of shrubs and trees in dry areas. Years with extreme, wet ENSO events may act as a window of opportunity for establishment of seedlings, which may then help to create a less-hostile environment for future generations of seedlings (Holmgren *et al.*, 2001). In semiarid ecosystems that have alternate stable states of vegetation (i.e., barren land, degraded savannah, shrubland, or dry forest), pulses of precipitation can play a role in moving the ecosystem from one stable state to another (Holmgren *et al.*, 2006). Interestingly, the process that leads to this type of phase shift may involve the periodic loss of top-down control of plant populations by herbivores. Pulses of precipitation allow plants to grow more rapidly than the numeric response of their herbivores, and this can result in a higher plant biomass equilibrium state, particularly when plants become less palatable with greater size (Scheffer *et al.*, 2008). However, accumulation of plant biomass during wet years can also lead to greater fuel loads, facilitating the ignition and spread of wildfires during contrasting dry years (Block and Richter, 2000).

The effects of increased precipitation can be even more complex. For instance, the dry ecosystems of the Gulf of California islands are influenced both by El Niño-induced influxes of primary productivity and by trophic inputs from the adjacent, highly productive marine ecosystem. Seabirds deposit guano on the islands, which enhances primary productivity increases during El Niño years, and carrion from seabird feeding (i.e., remains of marine organisms) act as a food resource for scavengers more generally (Sanchez-Pinero and Polis, 2000). Omnivorous rodents on these islands obtain marine food resources during dry years, but shift to seed consumption during wet years. So, on these islands, the omnivorous rodent guild experienced a fourfold population increase in response to one El Niño-induced pulse, and a subsequent crash when dry conditions returned. In contrast, granivorous rodents on the same islands experienced a more moderate population increase during the El Niño (1.6 times), probably mediated by food competition with the omnivorous species, but maintained a more stable population after dry conditions returned (Stapp and Polis, 2003). The importance of these direct (food resource) and indirect (nutrients *via* guano) spatial trophic subsidies illustrates the tight linkage between the marine and terrestrial realms in the California Gulf island system. This linkage tends to weaken during El Niño events (Stapp and Polis, 2003); thus, changes in ENSO could have effects on food web dynamics and biodiversity of these islands.

In areas where water is a major limiting factor, the periodic bursts of precipitation associated with ENSO events can exert significant bottom-up effects on multiple trophic levels. The expected effect of rapidly increased primary productivity is a rise in herbivore populations, which in turn positively affect both predator and pathogen populations. For instance, the 1992/1993 El Niño led to increased deer mouse density in New Mexico, US, allowing for a hantavirus outbreak (Holmgren *et al.*, 2006). Carnivorous bird populations respond to the variations in food resources by tracking these changes temporally (Jaksic *et al.*, 1992), and, at the community level, by forming looser guilds with divergence in diet (Jaksic *et al.*, 1993). However, top-down cascades can also be important, and tend to follow bottom-up effects with a delay.

During an El Niño event in the Chihuahuan Desert, Arizona, some herbivore species that were previously abundant disappeared, one novel species colonized the area, and other species experienced little change in their populations, while overall diversity remained stable (Brown *et al.*, 1997). This indicates that the net effect on populations is dependent on community-specific interactions within and among trophic levels. In addition, the state of the community prior to the change in precipitation is important in determining the effect of this change on the community. For example, although Galapagos finches generally experience a population boost during wet ENSO events, this boost can be mitigated by density-dependent effects if population levels had previously been high (Grant *et al.*, 2000).

Flooding

Floods cause catastrophic ecosystem change, with immediate abiotic and biotic impacts that may influence community regeneration in the long run. Erosion, changes in salinity, increased sediment in water, oxygen deprivation and habitat disruption can all have effects on biodiversity. For example, seabirds on the Galapagos lost their nests in flooding events during the 1982–1983 El Niño causing reproductive failure for the duration of this wet episode (Duffy, in Glynn, 1990).

The most important ecological effect of flooding is likely its influence on the structure of communities by providing periodic connectivity to ecosystems that are usually isolated. Floods can also maintain wetlands through periodic inundation, provide pulses of nutrients, sediment and species to areas that normally lack water connectivity, and can cause rapid habitat conversion. Rapid water flow through riverbeds can have a scouring effect, redistributing and reducing the abundance of zooplankton (de Paggi and Paggi, 2008). In some cases, resource inputs from flooding can maintain an ecosystem in a nonequilibrium state, or can speed up the process of succession (Ward *et al.*, 2003). Though not otherwise well studied with respect to ENSO, flooding can cause differential mortality of species due to different degrees of flood resistant adaptations. For example, during the 1997/1998 El Niño event, mangrove forests in a Tanzanian wetland experienced species-specific mortality and regeneration due to extensive flooding (Erftemeijer and Hamerlynck, 2005). Whether this short-term variation in survival translates into long-term changes in biodiversity is presently unknown.

Increased Sea-surface Temperature

Increases in SST have both direct and indirect consequences for biological systems. ENSO-related positive SST anomalies correspond with changes in the speed and direction of ocean currents, reductions in nutrient upwelling, and changes in the local environments of marine species.

Ocean Current Shifts

Dispersal of organisms by ocean currents is an important process in establishing and maintaining biodiversity in aquatic ecosystems. For example, the Hawaiian biota comprises a subset of Polynesian biota, and this similarity can be

attributed to movement of organisms on currents associated with El Niño events (Richmond, in Glynn, 1990).

El Niño-induced changes in ocean currents may lead to long distance dispersal of marine organisms from west to east. Genetic similarity between shallow water populations separated by 5400 km of ocean in the eastern Pacific (known as the Eastern Pacific Barrier, EPB) indicates that gene flow occurs between these populations (Lessios *et al.*, 1998). During non-El Niño years, parcels of water carried by the North Equatorial Counter-Current take 100–155 days to cross the EPB; in El Niño years this is shortened to 50–81 days. Given the known maximum time that larvae can stay in the plankton and successfully settle, the number of species able to colonize a new region may more than double under El Niño conditions (Richmond, in Glynn, 1990).

Nutrient Level Shifts

During non-El Niño years, the eastern equatorial Pacific Ocean comprises a large upwelling ecosystem, where the relatively shallow thermocline allows nutrient-rich cool water to rise along the west coast of South America. This tongue of cool water extends as far west as the International Date Line and along the coast of Central and South America between $\sim 10^\circ$ N and $\sim 20^\circ$ S. During ENSO events, upwelling decreases, and the area of cool, productive water is reduced to a pocket $\sim 10\%$ of its usual size along the South American coast. ENSO-associated reductions in upwelling also occur in the near-coastal southeast Atlantic Ocean through teleconnections. As nutrient upwelling is the first-order process governing ocean primary productivity, the effects of reduced upwelling have significant impacts on both marine and terrestrial biota. These impacts can be seen along the equator in the eastern Pacific, where primary productivity can fall to as low as 6% of normal during El Niño years, while in the remaining productive region primary productivity falls to 20–50% of normal (Barber and Kogelshatz, in Glynn, 1990). Such El Niño-induced changes impact heavily on, for example, fish and zooplankton-grazer species. The well-known short and longer-term fluctuations of anchoveta and sardine in the Pacific (Chavez *et al.*, 2003) highlight how species-specific traits are important in determining response to climate fluctuations.

Declines in small fish and other food source populations have bottom-up effects on higher trophic levels. For example, Christmas Island's great frigate bird population fell from 20,000 to fewer than 100 over the course of six months following the extreme 1982/1983 ENSO. While nest flooding and heavy rains may have caused some nestling death, adult abandonment of the island along with their young has been attributed to the disappearance of fish and squid as food resources. Also, multi-decadal records of species diversity and abundance in the Galapagos suggest that many marine species have yet to recover from the effects of the 1982/1983 El Niño event.

In upwelling ecosystems, water temperature and availability of nutrients are tightly linked. Therefore, seabirds, fish, and marine mammals within these ecosystems have evolved behavioral adaptations that enable these species to use thermal cues as indicators of areas of abundant food. Short-term responses of species to changes in productivity may then be mediated through responses to anomalous SST during ENSO

events. This results in a concentration of organisms residing in those areas where upwelling still occurs during El Niño events.

Coral Bleaching

Coral reefs are among the most diverse and productive ecosystems known and are one of the first to be severely affected by global climate change. The marked and rapid response of corals to global climate change is largely a result of the pronounced thermal sensitivity of most coral species (Graham *et al.*, 2006). Corals' physiological tolerance ranges between 18°C and 30°C , and many reefs exist at close to their upper temperature threshold. Against the baseline of rising SST associated with global climate change, the most catastrophic effects of climate change on coral reef communities are predicted to be through increasing the magnitude and frequency of extreme, periodic climate oscillations such as ENSO events (Reaser *et al.*, 2000). Increases in SST and solar irradiance have been heavily implicated in the widespread bleaching (loss of symbiotic zooxanthellae) and mortality of reef-building corals during ENSO events, and these effects are compounded when reefs already have reduced resilience due to other, often human-induced disturbance (e.g., cyanide poisoning, nutrient enrichment; Zhu *et al.*, 2004).

Over the course of a severe episode, corals may lose 60% to $>90\%$ of their symbiotic algae, and the remaining algae may lose 50–80% of their photosynthetic pigments (Glynn, 1996; Figure 4). Depending on the severity and duration of the bleaching event, corals may regain their obligate symbionts with the return of favorable conditions. Alternatively, individuals or entire assemblages may die. Coral mortality corresponds with an often-dramatic loss of coral species and reef cover of live corals. For example, two out of 12 coral species were virtually eliminated from Panama during the 1982/1983 ENSO (Glynn and Feingold, 1992). Also, coral mortality leads to loss of reef structural complexity due to reef disintegration. In addition to the initial loss of diversity, species such as the crown of thorns starfish are able to exploit remaining corals more effectively, at least in part due to

Figure 4 Example of El Niño-induced coral bleaching. Photo of a juvenile staghorn coral (*Acropora* sp.) at Pulau Pari, Thousand Islands, Indonesia, taken during the 1983/1984 El Niño event. Bleaching has started at the tips and at the periphery of the coral base (see Hoeksema 1991).

the corals' crustacean guards becoming less aggressive with the deterioration of their hosts (Glynn, in Glynn, 1990). Bioerosion and larval recruitment failure on damaged reefs also contribute to changes in species composition. On death, many corals are colonized by algae, which prevents coral regeneration and transforms these areas into non-reef building communities (McManus and Polsenberg, 2004). As coral reefs play host to some of the world's greatest biodiversity, loss of these habitats could have profound effects on that diversity. For example, in the Galapagos Islands direct or interactive El Niño effects, often mediated by coral reef deterioration, were recognized as the major threatening process for 29 of 45 species recognized as being at risk by the IUCN (Edgar *et al.*, 2010).

During the 1982/1983 El Niño, tropical eastern Pacific coral populations experienced up to 70–90% mortality; in the Galapagos Islands, mortality of most reefs was ~95%. Decimation of these populations has particularly profound effects in this region, where isolation from other reefs that could otherwise aid in repopulation prolongs recovery time. In coral reefs, the 1997/1998 bleaching event was the most severe and widespread ever recorded (Nyström *et al.*, 2000; Wilkinson, 2004). Some scientists fear that a threshold may already have been reached where reefs will not be able to cope with the increasing intensity and frequency of future bleaching events associated with ENSO-induced disturbances (Nyström *et al.*, 2000). McWilliams *et al.* (2005) reported exponential increases in the extent and intensity of bleaching with increasing SST anomalies in the Caribbean; a rise of only 0.1 °C resulted in 35% and 42% increases in the geographic extent and intensity of coral bleaching, respectively. Maxima of both are predicted to occur at SST anomalies of less than +1 °C; this would coincide with the most conservative projection for warming in the Caribbean by the end of the century. Bleaching will, therefore, probably be a chronic stress factor for Caribbean coral reefs in the future. The loss of live corals in turn has had a number of cascading effects on other taxa. Long-term

censuses of fish communities in Australia spanning bleaching events have shown species loss and distinct phase shifts in composition from pre- to postbleaching with no evidence of regeneration (Bellwood *et al.*, 2006; Garpe *et al.*, 2006). However, and interestingly, some evidence suggests that strong directional selection by frequent ENSO-induced thermal stress may lead to coral reef communities that experience less severe bleaching during subsequent ENSO events. While coral reef communities may become more resistant to thermal stress, the differential survivorship of corals and algal symbionts that leads to this resistance will likely also lead to large changes in species composition of coral reefs (Thompson and van Woesik, 2009).

Feedback and Conclusions

Interestingly, many of the ecological changes caused by extreme El Niño events may be self-reinforcing (see Figure 5).

Predicted changes in the frequency and severity of ENSO events have the potential to greatly alter biodiversity and ecosystem functioning (Harrison, 2000; Holmgren *et al.*, 2001; Holmgren *et al.*, 2006). In particular, severe ENSO-induced droughts can cause devastating forest fires with profound effects on ecosystem dynamics (Holmgren *et al.*, 2001). Although fires have always been present in Southeast Asia and in much of the world, population growth, habitat fragmentation, logging, changes in land-use, ENSO events, and the ubiquity of human ignition sources have increased the probability of catastrophic fires and are responsible for the catastrophic fires in 1982/1983 and 1997/1998 (Laurance, 1998; Laurance, 2003). In addition, both logging and previous fires increase the probability of future fires (Nepstad *et al.*, 1999), which are often exacerbated by build up of fuel from dead wood. Secondary fires are, therefore, much worse than initial fires (Cochrane *et al.*, 1999), leading to positive feedback.

Figure 5 El-Niño feedbacks on biodiversity. Blue arrows indicate increases, and red lines indicate decreases. Solid arrows are well-established connections, and dotted arrows are more speculative. So, El Niño causes decreased rainfall, which causes fires. The fires increase the severity of future fires, and these lead to a loss in biodiversity. Such fires also contribute CO₂ to the atmosphere, and if global climate change is linked to increased severity or frequency of ENSO-events, the feedback is positive. Likewise, increased sea-surface temperature (SST) is implicated in coral bleaching, which decreases local biodiversity as the community shifts. Because of trophic cascades and loss of stability, losses of biodiversity may also be reinforcing.

Ironically, these fires may also be contributing to greater global warming, which may, in turn, feed back into the ENSO cycle (Fedorov and Philander, 2000). Because of their scale of occurrence, fires now have the potential to more than double carbon emission in dry years (Malhi and Grace, 2000) and fires may have released the carbon equivalent of ca. 41% of world fossil fuel use in 1997/1998 (Cochrane, 2003). It is estimated that this, combined with other changes, has switched the tropics from a net carbon sink ($2.0 \text{ Pg C year}^{-1}$) to a net source ($0.4 \text{ Pg C year}^{-1}$) (Malhi and Grace, 2000). The release of large amounts of aerosols to the atmosphere can, furthermore, affect atmospheric stability and cloud formation and thereby reduce rainfall over large areas (Cochrane, 2003), thus compounding the risk of fire in these regions.

Conversely, increased precipitation in normally arid or semiarid regions can drive the restoration of degraded scrubland (Holmgren *et al.*, 2006). In areas that have been subjected to overexploitation, episodes of relatively extreme moisture in conjunction with decreased grazing pressure can lead the ecosystem to move to an alternative stable state of vegetation. In this manner, ENSO events may be partnered with land management strategies, with a favorable outcome for biodiversity in these regions.

ENSO is one climatic cycle among many that occur over various temporal and spatial scales. It is a natural phenomenon, and has been functioning for at least the past 130,000 years (Tudhope *et al.*, 2001). However, human activity may be causing ENSO events to become more frequent and extreme. As well, anthropogenic factors such as overharvesting, pollution, fragmentation, and edge effects not only worsen the direct effects of ENSO but also compromise the ability of ecosystems to maintain or re-establish levels of biodiversity following disturbance. There is little doubt that ENSO-induced disturbance, at least that mediated by human activity, has strong effects on biodiversity at many spatial and temporal scales, and the evidence suggests that the bulk of these effects are undesirable.

Acknowledgments

We thank M. Holmgren, I. Côté and an anonymous reviewer for constructive comments, B. Hoeksema for Figure 4, D. Austin for creating Figure 1, and the Dutch and Canadian National Science Foundations and the Institute for Advanced Study, Berlin for support.

Glossary

Chemoautotrophs Species that use inorganic compounds as a source of carbon and energy, and function as primary producers.

Decomposition The biotic breakdown of dead organic matter (detritus) by bacteria and fungi that releases carbon dioxide and nutrients for recycling.

Ecosystems Composed of species assemblages (producers and consumers) that interact with each other and their associated abiotic environment within well-defined natural or conceptual boundaries.

Food chains Composed of species that are connected by the flow of energy and material from producers to consumers.

Food webs "Flow maps" that depict connections among multiple food chains.

Functional groups Aggregations of species that perform similar ecosystem processes, such as grazers, suspension or filter feeders, leaf shredders, predators, and decomposers.

Photoautotrophs These species, such as green plants and some bacteria, use solar energy and inorganic compounds to synthesize organic matter as primary producers.

Primary productivity The rate of synthesis of organic matter by plants (biomass per unit area of habitat per unit time or, in some cases, biomass per unit volume per unit time).

Secondary productivity The rate of assimilation and growth by animals (biomass per unit area of habitat per unit time or, in some cases, biomass per unit volume per unit time).

Trophic cascades These occur when changes in the presence or absence (or shifts in abundance) of a top predator alter the production at several lower trophic levels; primary and secondary production at lower levels are alternately constrained or unconstrained by the feeding activities of consumers at upper levels.

Trophic levels Groups of individuals classified as primary producers or primary or secondary consumers within food webs; individuals feeding both as primary and secondary consumers are omnivores. A single species may be represented on more than one trophic level.

Introduction

Ecosystems are thermodynamically open, hierarchically organized communities of producers, consumers, and decomposers together with the abiotic factors that influence species growth, reproduction, and dispersal. These abiotic factors include the flow of energy and the circulation of materials together with the geological, hydrological, and atmospheric forces that influence habitat quality, species distributions, and species abundances. Energy flows through many species, and the way in which this flow affects the persistence of ecosystems is influenced by land-use changes, precipitation, soil erosion, and other physical constraints such as geomorphology.

Energy flow through ecosystems is essential for nutrients to cycle through food webs. These food webs are often subwebs of more complex species assemblages and may be only partial descriptions of more complex hierarchies of energy flows. The connections among species' interactions in natural food webs typically result in some important feedback loops and recycling of nutrients and materials within the conceptually defined boundaries of an ecosystem. Many species of producers are generalized in using solar energy (photoautotrophs) and form the basis of most food webs. Certain species live in deep, ocean thermal vents and use inorganic chemical compounds as energy sources (chemoautotrophs). The connections among producers and consumers are often complex and change with species age and size during an individual's life history. These food webs are diagrams that can function as "flow maps" to

document which species interact with other species, either directly or indirectly, as energy flows through the community and determines the movement of nutrients and other materials. This flow of energy is associated with the potential bioaccumulation of toxic chemicals that can be concentrated in predators who consume large amounts of prey that, in turn, have fed on large amounts of plants.

Different species have important functional values, such as for organic matter production (plant and animal growth) or organic matter breakdown (decomposition), oxygen production, nitrogen fixation, and nutrient cycling. These species have intrinsic values as the unique end products of evolution, and native species are likely to have adapted specific ways to respond to local or regional environmental changes or other physical disturbances. Conceptually, the loss of even a single native species, or the introduction of a nonnative species, could alter how the other remaining native species continue to perform different ecosystem functions. Disruptions of ecosystem processes are known to have occurred after certain well-adapted, native species were lost through local extinction following intense (pulse) or prolonged (press) disturbances. However, predicting species that are essential to ecosystem functions has generally remained difficult because information is lacking on many species interactions as well as on life history, adaptations to different disturbances, and dispersal abilities among key species. Ecosystem studies can provide a broad perspective regarding species relationships and recycling of essential nutrients. Species' shifts in patterns

of abundance (or local extinctions) following natural and anthropogenic disturbances can sometimes illustrate how certain key species regulate nutrient cycling and other ecosystem functions. Field testing of many concepts related to understanding the importance of key species in ecosystem functioning is just beginning. Results of these long-term ecosystem studies across a range of spatial and temporal scales can provide guidelines for the stewardship of biodiversity.

Ecosystem Boundaries: Inputs, Outputs, and Transformations of Energy

An ecosystem approach can be used to address many different questions spanning scales from the global biosphere to small ponds or patches of habitat. As the questions change, so do the boundaries and the complexities of species interactions within and among different compartments or across trophic levels. Ecosystem boundaries are often defined to include natural species assemblages and to analyze inputs and outputs of energy and materials for cross-site comparisons of efficiencies in energy transfers and studies of changing conditions. These analyses often take the form of mathematical models such as computer simulations or individual-based models of species and their specific functions within the biotic assemblage and environmental conditions under study.

One ecosystem may export nutrients and organic matter (stored energy) to other ecosystems so that cross-site linkages often become important. For example, in studies of nutrient cycling in terrestrial ecosystems, the definition of boundaries would likely have some compartments of organic matter production by living plants and their relationships with herbivores and carnivores. Macro- and micronutrient inputs would likely be derived from the atmosphere through dry deposition of particulates – nitrogen gas being taken up by some nitrogen-fixing species of microbes. Other sources of nutrients, especially phosphorus, would come from weathering and erosion of soil and bedrock deposits, with movement among other compartments derived from actions of wind and water. This combination of interactions illustrates the importance of defining clear boundaries for subsystems within the complete ecosystem so that measurements of movements (fluxes) among compartments can be measured accurately. Generally, ecosystems and their boundaries are abstractions that can only be useful and insightful when combined with sufficient knowledge regarding the natural history and general ecology of communities and their physical environment. There is wide recognition that a combination of direct field observation, experimentation, and modeling is essential when conducting ecosystem studies.

Currently, fundamental questions dealing with relationships between energy flow and the species-specific roles of organisms are attracting increased attention. For example, can results of controlled small-scaled (fine-grained) experimental studies of productivity be used to predict responses of other natural assemblages at larger scales (coarse grained) of ecosystem dynamics? Does energy flow through an ecosystem increase, decrease, or remain the same if one species goes locally extinct but the abundances of other “similar species” change rapidly to compensate for the lost species? Under what

Figure 1 Interactions among various factors constrain how ecosystems function. The climatic controls over inputs of solar energy and precipitation are two “forcing functions” which strongly influence how ecosystems operate. Land-use changes are also important in determining how water and nutrients move through the ecosystem and influence biodiversity. Nutrients moving among biotic and abiotic components are a type of “transfer function” that depends on abiotic and biotic factors (Modified from Schulze and Mooney, 1994).

environmental conditions do species substitute for one another and compensate functionally for the lost species? These and many other questions are beginning to be answered, but studies related to biodiversity and the persistence of species assemblages remain incomplete. A series of symposia during the 1990s dealt with the relationships between biodiversity and ecosystem functions (**Figure 1**) and stimulated many new ideas (Lawton, 1997; Palmer *et al.*, 1997; Naeem, 1998).

A Historical Perspective: The Ecosystem Concept

How energy moves from one group of species to another has been an active area of study at least since Charles Darwin and Alfred Russel Wallace first wrote in the 1850s about the interconnections among species. They were intrigued with the general proportions of population abundances that were thought to exist among different groups of large predators and their prey, and they emphasized competition and predation as important factors for regulating species interactions. These early observers lacked a conceptual approach to what was later viewed as ecosystem-level dynamics. Darwin’s studies of earthworms and their roles in soil development and his views on the roles of multiple species in the “tangled bank” metaphor stimulated others to consider how these many interactions could be viewed holistically. In 1887, Stephen Alfred Forbes described material cycles within lakes and used a table of predator–prey data to examine which fish species

consumed similar or different prey species in Illinois's rivers and lakes. Forbes drew his conceptual boundaries and predation matrix to coincide with the shoreline and emphasized putting the many pieces together in a type of system homeostasis in his new metaphor of the lake as a microcosm. This holistic view was taken up in a different way by E.A. Birge in 1915 with his work on heat budgets of lakes in Wisconsin. Birge measured inflows and outflows of energy, and in so doing he set the stage for viewing ecosystems in terms of their general physical attributes rather than numerous component parts. This "black box" approach allowed for observations at larger scales without full analysis of the controlling variables within the process under study.

The British ecologist, Charles Elton, recognized that food chains existed in the context of energy flow and nitrogen cycling from his early work with V.S. Summerhayes on Spitzbergen and Bear Islands. The sum of these chains formed a food web which Elton called "food cycles" and included in a diagram combining nutrient cycling and energy flows across landscapes scales. Elton built on earlier concepts of Victor Shelford and introduced the idea of a "pyramid of numbers" and a "pyramid of energy" that reflected general patterns of community organization. More individual plants and plant material (biomass) can usually be harvested in a plot than herbivores or the relatively rare carnivores. (Biomass is the weight of all individuals of a species or trophic level found in a square meter of habitat that can be converted into calories of energy.) These concepts of pyramids of biomass and energy led others to formalize ways to analyze these relationships. However, it was not until 1935 that Sir Arthur George Tansley first defined ecosystems as the "basic units of nature." Since then, ecologists have recognized and debated the importance of ecosystems as objects of study (Colley, 1993; Weathers *et al.*, 2011).

The Trophic Dynamic Concept

A major breakthrough came when Raymond Lindeman and G. Evelyn Hutchinson first proposed the concept of trophic levels (Lindeman, 1942; Hutchinson, 1948). Lindeman emphasized that aggregations of individuals rely on similar sources of energy and that this grouping of species provided a conceptual structure and a means for quantification and testing predictions. Lindeman built his concept on Elton's pyramid of numbers by emphasizing the importance of biomass as well as the linkages of "food chains" and "food cycles" as Elton had done. In addition, Lindeman used concepts from studies of biogeochemistry by V.I. Vernadsky. Vernadsky stressed integrating abiotic and biotic relationships among components of the biosphere, atmosphere, hydrosphere, and geosphere (Hagen, 1992). These new ideas on ecological efficiency of energy transfers within the biosphere were being developed by Lindeman's mentor, G.E. Hutchinson at Yale University, in his long-term studies of Linsley Pond, Connecticut. Hutchinson introduced the use of P-32 in studies of phosphorus cycling with his early work on the biogeochemistry of Lindsey Pond in Connecticut. These isotopic studies made it possible to determine the rates of nutrient uptake and recycling by grazing zooplankton. Lindeman's trophic

dynamic concept recognized that groups of species both "co-act" and "re-act" in their relationships with each other and with their abiotic environment.

Lindeman also emphasized that these patterns of productivity change as the biotic and abiotic community develops over time through succession. Based on his own detailed studies at Cedar Bog Lake, Minnesota (and other studies by Chauncey Juday on Lake Mendota, Wisconsin, who was actively studying lake productivity with E.A. Birge), Lindeman proposed that lake productivity increased during succession as nutrients accumulated in the basin during eutrophication. This natural aging process of a lake ecosystem was thought to reach a climax stage and undergo senescence before developing into a bog forest ecosystem. As with the trophic dynamic concept, some of Lindeman's thinking on patterns of change in productivity over time was influenced by earlier studies by G.E. Hutchinson and his colleagues on Linsley Pond, Connecticut. Lindeman (1942) noted that their work suggested that "these generalized changes in the rate of production may be expressed as a sigmoid curve showing a rough resemblance to the growth curve of an organism or of a homogenous population" (p. 409). Such analogies between ontogeny of individuals, populations, communities, and ecosystems were commonly used during that time period. However, as more accurate data on rates of sedimentation, nutrient cycling, and productivity became available as a result of the improved development of isotopic dating, the generality did not hold up and multiple patterns of Lake Eutrophication were later documented. Hutchinson and one of his students, E.S. Deevey, helped develop the use of radioactive isotopes (C-14 and Pb-210) for determining rates of deposition of sediments from cores of lake sediments. This early work led to the field of paleolimnology that has contributed much to the recent studies of climate change, land-use shifts, and the effects of people on ecosystems. Prior to radiocarbon dating techniques it was not possible to be certain about patterns from one region to another being caused by certain events. With the use of C-14 to cross-correlate major changes in the sedimentary records, these "floating" chronologies became strong evidence for tracking rates of changes across regional landscapes.

As a result of studies in many different types and locations of lakes, the patterns of eutrophication varied and reflected land-use changes as well as natural processes of accumulation of carbon and nutrients over time. Some lakes such as man-made reservoirs were observed to begin with relatively high concentrations of dissolved nutrients derived from leaching of inundated soils and microbial breakdown of organic matter in the flooded basin. These high nutrient concentrations often diminished over time and resulted in lower production. This pattern is the opposite of what was observed in changes from low to high production in many natural lakes (from oligotrophy to eutrophy). More recently, the rates of eutrophication have been documented to respond to foodweb dynamics in trophic cascades. Removal or addition of top predators (such as large-mouth bass) altered the prey populations of small species of consumers that, in turn, changed the number of grazers and the rate of algal production. Whole-lake experiments conducted in Wisconsin led to a new understanding of how phosphorus could limit algal growth and how the entire food web could affect rates of primary production.

As a result of these studies, it was recognized that recreational fishing can be managed by harvesting many of the larger fish and thus changing rates of algal growth and removing nutrients in both reservoirs and natural lakes. As discussed later, this biomanipulation links fisheries management and lake management to control of nutrient cycling and plant growth. Rainfall, runoff, and transport of sediments from the watershed (as well as inputs from wastewater treatment plants) can add various amounts of nutrients over time in lakes and wetlands. Consequently, the rate of eutrophication varies from one watershed to another depending on land uses, slopes, and climate.

The concept of trophic dynamics and its focus on transfers of energy between trophic levels was not widely accepted until a new postwar influx of investigators began detailed studies of energetic and nutrient cycling. Several questions have persisted for decades: How can energy flow regulate the number of trophic levels within an ecosystem? How does one group of consumers regulate the numbers of individuals and energy flow in other trophic levels? Which nutrients limit plant growth and how are consumers involved in recycling nutrients? These questions and many others were rapidly taken up by ecologists such as G. Evelyn Hutchinson, Eugene Odum, and Howard Odum and their students in the 1940s and into the 1970s.

After considerable debate and continued developments of the concept, many ecologists today rely heavily on models and field experiments using modifications of Lindeman's approach. Some still have concerns about fundamental issues regarding how trophic levels are defined relative to the complexities of natural food webs. As a result, there are various definitions of what constitutes a trophic level. Some prefer to use a more general term, trophic position, to indicate relative feeding relationships but do not measure transfer efficiencies across trophic levels. Because most descriptive field-based studies of food webs really are studies of subwebs, and therefore are incomplete, a thorough test of predictions regarding food chain length or long-term stability relationships derived from trophic models is usually not feasible except in very simple food webs or in laboratory studies.

Conceptually, the predictions of how energy flow regulates trophic dynamics are relatively straightforward. First, some of the initial energy entering the first trophic level is lost by reflectance from the plants, lost as heat, expended in metabolism and evapotranspiration, or lost because of a less than complete coverage of foliage (leaf area) or algal volume. Thus, some warming occurs by energy absorption by the physical habitat (e.g., soil, rock, or water). Then, from constraints imposed by the second law of thermodynamics, energy is lost at each step in the flow of energy from the first trophic level to successively higher levels within food webs. The use of solar energy or chemical energy by primary producers and the consumption of plants and animals at higher trophic levels are relatively inefficient because some energy is lost to metabolism and as heat at each transfer across trophic levels. The total energy flow through the plant trophic level is termed gross primary productivity (GPP). Once the energetic costs of respiration are subtracted from GPP, the remaining energy is called net primary productivity (NPP). This NPP is usually a very small portion of the available solar energy that entered

the first trophic level. NPP is the only amount available for transfer to upper trophic levels. In some ecosystems, there is an "energy subsidy" provided by inputs of organic matter from another ecosystem. For example, leaf litter entering a stream, lake, or open cave can be an essential source of stored energy for use by detritivores in a different ecosystem than the forest ecosystem in which it was produced. In all energy transfers between trophic levels, the assimilation of energy is variable but generally of low efficiency. Typically, efficiencies (output:input ratios) are less than 10%, but higher values are known for some food webs. The consistently low values that were first measured in ecological studies in the 1940s and 1950s led to the hypothesis that the number of trophic levels within any food web was determined primarily by the amount of incoming energy and the efficiency of energy transfers.

Food Webs and Trophic Levels

Empirical studies demonstrate that most food webs contain fewer than four trophic levels. However, the number of trophic levels is not a consistent measure because of the complexity of feeding relationships over time and space, the mobility of consumer species, and the movement of food resources across ecosystem boundaries. Many species vary in how they obtain their energy and how efficient they are at different stages of their life histories and under different conditions. Among consumer species, many rapidly growing juveniles or reproductive adults require high-quality, nutrient-rich foods. These same individuals typically feed on lower protein foods when they become nonreproductive adults. Numerous species are omnivores and feed on plants and animals from different trophic levels. Because of these complexities, there has not been complete agreement on how to operationally define trophic levels.

The transformation of inorganic elements into organic matter requires energy to be converted into biomass by species of algae, green plants, and a few types of bacteria. These micro- and macroautotrophs are often represented by many species. The degree of similarity (niche overlap) in their abilities to produce and to store organic matter is important in predicting the consequences of any losses of species. Many species have evolved into persistent assemblages that store carbon and nutrients such as nitrogen and phosphorus. Energy stored in the form of plant-produced organic matter is later passed on directly to grazing species and then indirectly to predators within food webs.

Efficiency of energy transfer from one trophic level to the next higher level is of fundamental importance in understanding conceptually how different ecosystems function. Measures of efficiency, however, are only a part of the explanation for why some ecosystems have longer food chain lengths than others. Relatively "inefficient" food webs with few trophic levels appear to be adapted to certain types of frequent disturbances. Ecologists realize that a single explanation or mechanism is unlikely to account for all the various complexities that exist in determining how ecosystems are organized in terms of energy flow. However, comparisons among well-studied ecosystems and their numbers of trophic levels (food chain length) can provide a useful basis for predicting vulnerability of food webs to major disturbances and movement of toxins such as mercury and other heavy metals.

Analysis of guilds and that of functional groups are different approaches used to study shifts in feeding behavior and to complement trophic-level analysis. Guilds are defined as assemblages of species or individual age classes that share a common source of energy at any given time (e.g., nectar-feeding birds and bees and insect-feeding birds and spiders). Functional groups are defined as being similar in their mode of feeding (e.g., filter feeders, shredders, and pursuit predators), but individuals may use a variety of different sources as resource availability shifts. Thus, individuals of a single species may be distributed over several trophic levels and belong to different guilds and functional groups during each individual's life span and reproductive period. As nutritional requirements change and the availabilities of different types of food resources also change, individuals can often adapt to find different available sources of energy. Analyses of similarities in these adaptations and the degree of overlapping functionality are used to understand the degree to which producer and consumer species are interdependent. Numerous complex linkages (e.g., herbivory, predation, decomposition, parasitism, and mutualism) imply that few species are likely to be complete substitutes for other species. As discussed later, some species may interact positively, negatively, or neutrally in association with other species. Such complex relationships among species, especially under changing environmental conditions, complicate field experiments and make predictive models difficult to test fully.

Controls of Energy Flow in Food Webs

A small increase in species richness can have a large effect on how energy flows through food webs. The main features are the number of linkages among species and, especially, the type and strength of those linkages (Paine, 1969). For example, a simple trophic structure would be a linear series of three species (A–C) in a food chain with one species in each trophic level (Figure 2). Thus, a single species of plant is consumed by a single species of herbivore, which is consumed by a single predator species. Although analysis is relatively definitive in these types of communities with few species, this simple food chain structure may preclude consideration of some questions

of general concern, such as resiliency of the assemblage following a disturbance and species loss.

If one more plant species is added (D) to a simple community, then this slightly more species-rich food web provides some important additional dynamics in terms of alternative pathways for energy to flow. Moreover, the herbivore (B) can switch from one food resource to another and this additional complexity increases generality and realism incrementally. With two herbivore species (B and C) the food web is more complex and the predator (A) has a choice of prey resources. Even with the same number of species, much more realism is added by considering the predator (A) to be an omnivore, and even more is added if the predator and one of the herbivores (C) are also cannibalistic. These simple diagrams show how quickly the types and numbers of linkages (connectance) within food webs can change the dynamics of energy flow even with only a few species. This last example is typical of some low-diversity stream food webs on isolated tropical islands currently under study and discussed later.

Ecosystem Analysis

General rules regarding the relationships between energy flow and the control of food web complexity are currently incomplete. In some habitats a complex relationship apparently does exist among the total annual amount (and seasonal distribution) of energy, the nutrient inputs to ecosystems, and the number of different species in a habitat. In other habitats there is no evidence for a cause-and-effect relationship among the rate of energy flow, species growth and productivity, and the number of species in an ecosystem. Other likely variables include evolutionary time and biogeographical distributions as well as the frequency and intensity of disturbances. The particular species composition of a food web may also alter productivity. Empirical evidence for predicting the importance of species-specific relationships is increasing, but methods for establishing which species regulate ecosystem functions remain controversial. Currently, only a few studies have focused on the species-specific roles to determine which species have unique roles and how these roles shift as environmental conditions change.

Figure 2 Energy flow through simple food chains and webs. Small increases in species number lead to high trophic complexity as connectance (arrows) and cannibalism (looped arrows) increase. The number and strength of connections among species are more important in regulating the flow of energy through food webs than simply the number of different species in food webs.

Although recent experiments have examined some fundamental relationships, we do not have a full understanding of the effects of varied energy inputs on the richness of consumer species that naturally coexist in ecosystems. For example, in most tropical forests and coral reefs there is generally a high number of species, but the cause and effect of this species diversity are open to different interpretations other than the potential importance of relatively high and continuous inputs of energy.

At the earth's surface, the annual, seasonal, elevational, and latitudinal distribution of solar energy provides varied inputs of energy to deserts, grasslands, forests, wetlands, lakes, rivers, and oceans. Generally, energy always flows through ecosystems but does so at different rates under different global geographical locations and local conditions of slope and aspect. Depending on the latitude, ecosystems generally receive a seasonally pulsed or a continuous annual supply of solar energy for primary producers. The rate of energy flow and associated biological productivity are dependent not only on the availability of energy but also on water, on combinations of different macronutrients (nitrogen and phosphorus) and micronutrients (trace elements such as iron, manganese, and silica), and on the presence of an assemblage of interactive plant and animal species. Some natural food webs in extreme environments, such as hot springs, saline lakes, caves, or certain deep-sea thermal vents, have relatively simple linear food chains and have species adapted for specific habitats. For example, dark, closed caves that are deep underground only receive indirect sources of detrital energy from sunlit surfaces aboveground and are typically characterized by a relatively low number of endemic species not found on the surface. Deep-sea thermal vents in the oceans rely solely on chemical energy derived from microbial breakdown of gases such as hydrogen sulfide and are characterized by sulfur bacteria and unique consumer species. These simple ecosystems continue to provide an opportunity to test some fundamental concepts regarding food webs and energy flow relationships.

Multiple Energy Pathways

It has been evident since Lindeman's work that energy travels along different pathways and includes microbial species and macro-species in various interconnected relationships. Experimental assemblages are now being widely used to provide some insights into which mechanisms control ecosystem dynamics. There is evidence for biotic control mechanisms (interspecific competition for resources, predation, parasitism, and mutualism), abiotic controls (nutrient limitation and frequent and/or intense disturbances), and combinations of controls in different ecosystems. These studies have also provided important insights regarding two main energy pathways. The distinction between direct, solar-driven, photosynthetically based food webs and indirect transfers of stored energy in the form of detritus (that can be wind driven or washed into habitats) has sorted energy flows into two main classes. The earliest work on ecosystems recognized this bimodal classification and it remains an important organizing framework in linking aspects of terrestrial and aquatic ecology.

The importance of organic detritus as a means for storage of energy was recognized by studies of Jerry S. Olson in the 1960s

at Oak Ridge National Laboratory on the carbon cycle. Analysis of time lags requires an understanding of how rapidly organic detritus accumulates and then breaks down to recycle carbon, nitrogen, phosphorus, and other materials. These insights are critical in current discussions regarding carbon dioxide accumulation in the atmosphere as fossil fuels are burned (i.e., coal, oil, and natural gas taken from storage that accumulated over geological timescales and are now being rapidly cycled back into the atmosphere following combustion). Debates regarding global warming, the greenhouse effect, and where the "missing" carbon is in the present-day ecosystem require a thorough understanding of the entire biosphere and the carbon cycle as it relates to other nutrient cycles.

Studies of deep-sea vents and hot mineral springs illustrate another distinct class of ecosystems. This food web is not solar driven but depends on chemical energy sources used by chemosynthetic microbes. Geologic sources of hydrogen sulfide and other gases provide examples of chemical energy pathways that may well have been the first modes of ecosystem formation by the earliest microbial species on Earth before the evolution of photosynthetic species. Various lines of evidence, such as the banded iron formations in pre-Cambrian rock strata, indicate that the earliest atmosphere lacked oxygen, suggesting that chemoautotrophs dominated the first phases of evolution. Once oxygen-producing photoautotrophs evolved and dominated the oceans and lakes (and later developed terrestrial forms of green plants), their high levels of primary productivity resulted in an accumulation of oxygen in the atmosphere and a decrease in carbon dioxide (possibly through carbon uptake and storage by plants and deposition of sedimentary limestones). This early shift into a photoautotrophically based ecosystem apparently put the chemoautotrophs at a competitive disadvantage in an oxygen-rich environment. These remnants of the earliest species of microbes coexist with specialized species of tube worms, shrimps, and crabs that now dominate deep-sea thermal (DDT) vents where these chemoautotrophs use inorganic chemical compounds as energy sources.

Lake Ecosystems

To illustrate the flow of energy through ecosystems it is useful to consider some examples derived from lake studies. These convenient habitats have been used for comparative ecosystem studies because distinct boundaries provide clear definitions of inputs and outputs (**Figure 3**). The main boundaries include any inflowing and outflowing rivers as well as the lake surface-atmosphere and the sediment-water interfaces and also shorelines and topographic ridges (that delimit drainage basins). Water temperatures, nutrient inflows and outflows, and mixing and transport processes all influence species distributions and abundances in generally predictable ways.

Solar energy transformed into organic matter through the process of photosynthesis is the main source of energy for most ecosystems, especially in large lakes. Different sizes and types of plants in lakes vary greatly in their rates of productivity. For example, in shallow-water ecosystems solar energy can be used by microphotoautotrophs (attached algae or suspended phytoplankton) and macrophotoautotrophs (pond weeds such as cattails and water lilies). The ratio of the biomass of organisms

Figure 3 A nutrient-rich lake ecosystem and the flow of energy and materials through major compartments. The inputs of dissolved nutrients and particulates (leaf litter and suspended organics) move through the lake ecosystem at a rate determined primarily by the amount of solar energy entering from the surface of the lake, the stored energy in the form of organic matter inputs (for bacteria, fungi, and detritivores), and through-flow of water. Productive lakes can be either sources or sinks of nutrients relative to downstream river and lake ecosystems, depending on their uptake and storage of energy and nutrients. Shallow lakes have a higher surface to volume ratio than deep lakes and are usually more productive because a larger proportion of their volume receives solar energy inputs. Winds mix nutrients from bottom waters and often circulate limited concentrations of dissolved phosphorus that flux from the deeper sediments. Energy transformations from solar input to green plants to herbivores and carnivores are essential for nutrients to move through the food web and be recycled (reproduced from Covich MA, Palmer, and Crowl TA (1999) The role of benthic invertebrate species in freshwater ecosystems. *BioScience* 49: 119, with permission from American Institute of Biological Sciences).

relative to their rate of production is termed “biomass turnover time.” Biomass is generally measured by multiplying the number of individuals in a population by each individual’s weight. Turnover time is related to how rapidly organisms increase in biomass during their life span. Rapid turnover is associated with high rates of productivity by small, fast-growing individuals of plants and animals. Small species with rapid turnover usually exploit resources at relatively fine spatial scales.

Importance of Depth and Spatial Heterogeneity

Different wavelengths of light energy penetrate into waters of different depths. Shade-tolerant species of plants living in deep water (or in deep shade of the canopy trees in terrestrial ecosystems) have distinct physiological adaptations that allow them to obtain sufficient energy to grow and reproduce even at low light intensities. The range of wavelengths that is used by plants is light visible to the human eye. This range of visible light (between approximately 400 and 700 nm) is termed photosynthetically active radiation. Short wavelength (ultra-violet light) and long wavelength (infrared light) are not used in photosynthesis but are important in regulating floating and emergent aquatic plants (or terrestrial plants in other ecosystems) because ultraviolet radiation degrades organic molecules and infrared increases leaf temperatures. Daytime warming from the sun is essential for some species to survive, especially insects and cold-blooded vertebrates (poikilotherms). Other transfers of solar energy are essential to various Lake

Ecosystem processes (e.g., sediment and nutrient transport by wind and water). Work done by solar-generated winds mixes the lake and thereby influences nutrient cycling. Similarly, wind-driven currents disperse planktonic larvae and aerate deeper waters. Winds also increase salinity through evaporation.

Consumer species are limited by the availability of plant-derived organic materials (or microbially derived organic materials from chemoautotrophs). The well-mixed, brightly lit, open water (pelagic zone) is dominated by small species of zooplankton that are well adapted to feed on suspended phytoplankton. Microbial breakdown of dead organic matter (detritus or seston) and grazing on algae by numerous invertebrate and vertebrate species function to recycle nutrients in the open waters. In other distinct habitats such as the shallow littoral zone near the shoreline, a vegetated zone is dominated by invertebrate species that feed on larger, rooted plants that have a slower turnover rate compared to the small, suspended algae. Some species of fish live in the littoral zone while young and move in and out of the pelagic open waters as they grow larger. As these predators increase in size, they switch from feeding on invertebrates and small fishes to consuming larger fish and crayfish prey.

Internal and External Nutrient Cycling

Ecosystems are generally “open” with regard to external additions of nutrients from the atmosphere and from catchment

basins. Deserts, grasslands, forests, and wetlands as well as most lakes and rivers continue to receive new supplies of nutrients from precipitation (rain and snow), from dust and eroded soils that are carried to the ecosystem by wind and water, and from human-derived fertilizers, sewage effluent, air pollutants, and other agricultural and industrial wastes. Decomposers recycle essential elements for continued productivity by other species. As a result of rapid decomposition, some ecosystems can be relatively “closed” in that nutrients may be rapidly recycled internally so that these nutrients remain within the ecosystem’s boundaries and are not transported or lost to other ecosystems. Nutrients can recycle internally from temporary storage in living tissue (biomass), detritus, or storage in soils and sediments.
